Brass; Process for "tempering" — C. A. Perrin, Fr. Pat. 393,629, Oct. 30, 1907.

THE brass to be "tempered" is heated to a cherry-red heat, and then plunged into a large quantity (100 litres) of a liquid containing copper sulphate, to which other substances may also be added. A suitable composition for the quenching liquid is: Copper sulphate, 250 grms.; plumbago, 100; gum arabic, 250; borax, 200; and magnesium sulphate, 200 grms.; "dissolved" in 10 litres of water.—A. G. L.

[Tin] Metal; Process for the treatment, fusion, and detection of — from stanniferous products of all kinds, especially from the finely-divided metal obtained by electrolytically detinning tin-plate. H. Mennicke, Fr. Pat. 393,364, Aug. 14, 1908. Under Int. Conv., July 10, 1908.

THE finely divided tin obtained by electrolytically stripping tin-plate is compressed into metallic grains by agitation under water in a vessel provided with an internal agitator, and to which fresh water is continually supplied to wash away the alkaline liquid originally adhering to the metal. After about 2 hours, the heavy grains of tin are separated from the light dross and from the liquid, and are stored under oil. They are next mixed with 5 per cent. of anthracite free from sulphur and ash, or with charcoal, and with 20 per cent. of sodium carbonate, and are fused in a small crucible furnace, the temperature after the first half-hour being raised to 1000° C. for 15 minutes, and then kept at 750–800° C. for another half-hour. The escaping gases are washed with water to condense the small amount of tin volatilised. The slag is dissolved in hot water, the solution containing sodium stannate is filtered, and stannic hydroxide precipitated by a current of carbon dioxide. After filtration, sodium hydroxide is regenerated in the liquid by treatment with lime, and is used for the electrolysis of a fresh batch of tin-plate.—A. G. L.

Cinders, slags or other fused materials; Process for mixing reagents or other substances with — Société des Chèvres de France, Fr. Pat. 393,813, Nov. 6, 1907.

FINELY divided materials are injected into fused substances issuing from a furnace by means of a blast issuing from a tuyère. Thus, e.g., ground sand may be mixed with the slag from a copper furnace, in order to yield a material suitable for the manufacture of high-grade ferro-silicon or other silicon alloy.—A. G. L.

Ores and other materials; Metallurgic treatment or smelting of — K. Birkeland, Christiania. Eng. Pat. 913, Jan. 14, 1908.

SEE FR. Pat. 386,059 of 1908; this J., 1908, 756.—T. F. B.

Steel from chromiferous pig iron; Process for manufacturing — F. D. Carney, Steelton, Pa., U.S.A. Eng. Pat. 16,093, July 29, 1908. Under Int. Conv., Aug. 28, 1907.

SEE U.S. Pat. 902,052 of 1908; preceding.—T. F. B.

Metallic plating, coating, or fouling from metallic or other surfaces; Removal of — T. R. Bayliss, Northfield, W. R. Hodgkinson, Blackheath, J. H. Harcastle, Lee, A. H. Coote, Westcombe Park, and R. A. E. Payne, Edgbaston, Assignors to King's Norton Metal Co., Ltd., London. U.S. Pat. 908,937, Jan. 5, 1909.

SEE FR. Pat. 387,117 of 1908; this J., 1908, 818.—T. F. B.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

(1.)—ELECTRO-CHEMISTRY.

Ozone; Formation of — at rotating anodes. F. Fischer and K. Bendixsohn. Z. anorg. Chem., 1909, 61, 13–39.

IT has been shown previously (this J., 1907, 156, 208) that by the electrolysis of sulphuric acid, using special platinum electrodes, in which only a narrow strip of the metal is exposed, the remainder being covered with glass, oxygen containing 23 per cent. by weight of ozone can be obtained by cooling the interior of the electrodes with water of 13° C., and containing 28 per cent. by cooling with calcium chloride solution at –14° C. The present authors have tried the effect of using rotating electrodes. Three kinds of electrodes were tried:—(1), wire electrodes, in which two fine platinum wires were sealed into projections on a glass stem; (2), roller electrodes, in which pieces of platinum foil were sealed into the opposite sides of an enlargement at the end of a glass stem, somewhat of the form of a thermometer bulb; (3), disc electrodes, in which a circular piece of platinum foil was sealed between two glass discs, and the whole sealed on to the end of a glass stem at right angles to the axis; in one case the exposed strip of the foil was continuous, but in another, gaps were made. In all forms of electrodes, the glass stems were hollow and filled with mercury, by means of which contact was made. The results of experiments with these electrodes showed that higher yields of ozone were obtained with rotating than with fixed wire electrodes. With the foil electrodes, on the other hand, higher results were obtained when the electrodes were at rest than when they were rotated. The most important condition for the attainment of high yields appears to be that the exposed portion of the platinum be extremely thin. In one experiment with a disc foil electrode, in which gaps had been cut in the exposed strips of platinum, oxygen containing 23.4 per cent. by weight of ozone was obtained without special cooling.—A. S.

Benzoic acid; Conversion of — into salicylic acid [by electrolysis]. G. Bargellini and G. Inghilleri. Rend. Soc. Chim. di Roma, 1908, 6, 333–334.

SALICYLIC acid was produced by subjecting to electrolysis with a current of 8 volts, a solution of 10 grms. of benzoic acid in 75 c.c. of acetic acid and 300 c.c. of water. Electrolysis was effected in a glass beaker on the bottom of which was a layer of mercury of 78 sq. cm. area, which served as cathode; the anode consisted of a piece of platinised platinum foil of 7 sq. cm. area. The most favourable temperature was found to be 50°–60° C.; below 50° C. little or no salicylic acid was formed, whilst above 60° C. a red resin was produced, which adhered to the anode. Under similar conditions, salicylic acid yielded a compound, melting about 200° C., probably a dihydroxybenzoic acid; phthalic acid also yielded probably a dihydroxy-derivative.—A. S.

Reducing benzoic and salicylic acids. Mettler. See XX.

Regulations, dated Dec. 23, 1908, for the generation, transformation, distribution, and use of electrical energy in premises under the Factory and Workshop Acts, 1901 and 1907. Statutory Rules and Orders, 1908. No. 1312. (Price 1d.)

PATENTS.

Insulating and other purposes; Manufacturing artificial plates for —. E. Weidinger, Höchst, and H. Kahn, Frankfurt a/M, Germany. Eng. Pat. 28,117, Dec. 20, 1907.

BASIC materials, such as finely-ground china clay and disintegrated asbestos, are brought to a plastic condition by the addition of a solution of water-glass, with or without a small quantity of an anhydrous binding medium, such as indiarubber solution. Powdered stone, or an appropriate colouring material, may be added to the basic substances employed, in order to increase the density of the finished material. The water-glass solution, and also any moisture contained in the basic materials, acts upon the clay and asbestos, forming hydrated silicates, without the employment of heat, thus producing an insulating substance free from pores.—B. N.

Insulating composition; Solid —. Standard Varnish Works. Fr. Pat. 393,217, Aug. 11, 1908.

THE material, which is not attacked by mineral oils, is composed of castor oil, a fossil gum, such as kauri gum, and rosin.—O. F. H.

Electrolyte. E. C. Broadwell, Assignor to J. W. Meaker, jun., Chicago, Ill. U.S. Pat. 905,837, Dec. 8, 1908.

THE electrolyte consists of a solution of an inorganic salt and a carboxylic sulphonic acid salt of the metal to be deposited, e.g., zinc sulphate and zinc naphthalenedisulphonate. The electrolyte may also contain a salt of a metal to alloy with the metal deposited.—O. F. H.

Pigments by electrolysis; Art of producing —. E. D. Chaplin, Boston, Mass., Assignor to International Lead Companies. U.S. Pat. 906,102, Dec. 8, 1908.

LEAD is dissolved in an electrolytic cell in which the electrolyte is separated by electrolysis into a solvent of lead and an alkali hydroxide. An oxidising agent is added to prevent the formation of insoluble salts of lead, and the lead solution withdrawn. The alkali hydroxide is also withdrawn and converted into carbonate, which is used to produce white lead directly from the lead solution.—O. F. H.

Lead salts by electrolysis; Art of producing —. E. D. Chaplin, Boston, Mass., Assignor to International Lead Companies. U.S. Pat. 906,103, Dec. 8, 1908.

LEAD ore or impure lead is made the anode of an electrolytic cell, the lead and other metals passing into solution in the electrolyte in the presence of an oxidising agent to prevent the formation of insoluble lead salts. The electrolyte is continuously withdrawn, the metals other than lead recovered in metallic form by contact deposition, and the lead converted into the desired lead salt, e.g., precipitated as lead carbonate.—O. F. H.

Electrolytic apparatus. E. D. Chaplin, Boston, Mass., Assignor to International Lead Companies. U.S. Pat. 906,104, Dec. 8, 1908.

A NEUTRAL solution (electrolyte) passes from a storage tank to a series of electrolytic cells at a lower level. The solutions from the anode and cathode compartments of the electrolytic cells are discharged into two storage tanks at a still lower level, and thence pumped up to two tanks above the neutral solution tank. The anode and cathode solutions then pass to precipitating vessels which have outlets to a filter tank and to the neutral solution tank.—O. F. H.

Silicon; Method of producing —. H. N. Potter, New Rochelle, N.Y., Assignor to G. Westinghouse, Pittsburg, Pa. U.S. Pat. 908,130, Dec. 29, 1908.

CRUDE silicon, containing silicon carbide, is purified by maintaining it in a fused state in an electric furnace on a bed of silica, thus oxidising the carbon and reducing some of the silica. The same furnace is previously employed for preparing the crude silicon.—F. SOBX.

Silicon carbide; Method of producing —. F. J. Tong, Assignor to The Carborundum Co., Niagara Falls, N.Y. U.S. Pat. 908,357, Dec. 29, 1908.

THE process consists in embedding an electric resistance conductor in a porous charge of silicious and carbonaceous material, initially heating the charge by the passage through it of heated gases or by the combustion of an excess of carbon in it by means of oxidising gases, and then further heating the charge sufficiently to produce silicon carbide by passing a current through the resistance.—F. SOBX.

Electric furnace. P. L. T. Héroult, La Praz, Assignor to Soc. Electro Metallurgique Française, Froges, France. U.S. Pat. 908,407, Dec. 29, 1907.

THE electrode for the furnace passes through a stuffing-box provided with a packing of loose granular conducting material, and enlarged towards its outer end so that the withdrawal of the electrode tends to loosen the packing. Means are provided to pass a current through the stuffing-box to the electrode.—A. G. L.

Alkali-metal amalgams; Apparatus for decomposing — [electrolytically]. C. F. Carrier, jun., Elmira, N.Y. U.S. Pat. 908,545, Jan. 5, 1909.

THE apparatus comprises a vessel containing the amalgam, an electrolyte in contact with the amalgam, and a body of graphite, consisting of a number of spaced plates, in contact with the amalgam and the electrolyte. The bottoms of the plates are recessed, and an inlet for the amalgam, and an outlet for the mercury, are arranged on opposite sides of the plates. Metallic weighting and spacing bars are bolted between the tops of the graphite plates, and assist in making contact between the plates and the amalgam.—B. N.

Circulating-pump for electrolytic cells. C. F. Carrier, jun., Elmira, N.Y. U.S. Pat. 908,546, Jan. 5, 1909.

A MERCURY conduit extends between the decomposing and oxidising compartments of an electrolytic cell having a mercury cathode, the conduit being provided with "a pump-well," or casing, "opening upwardly from the conduit," and containing a "rotor," the conduits, casing, and "rotor" consisting of non-metallic material, such as vitrified earthenware. The "rotor" is less in diameter than the well, the former "comprising a cylinder having substantially radial vanes projecting from its lower surface and terminating at the periphery of the cylinder."—B. N.

Ozone; Apparatus for preparing —. D. E. Parker, Niagara Falls, N.Y. U.S. Pat. 909,017, Jan. 5, 1909.

THE ozone is prepared by electrolysing molten sodium peroxide which is fed from a hopper provided with a worm feed into a hot-water jacketed melting pot, into which the electrodes conveying the current dip. The pot is supported on trunnions so that it can be tilted, to discharge the molten contents, and the hopper is supported on a bracket, above the pot and can be moved aside, when it is desired to tilt the pot.—W. H. C.

Ozone; Apparatus for the generation of —. Cie. pour la Fabrication des Compteurs et Matériel d'Usines à Gaz. First Addition, dated Aug. 14, 1908, to Fr. Pat. 380,713, July 24, 1907.

THE transformer, mounted on a suitable board which may be attached to a wall, may have an iron-clad or open core, the ends of the latter being expanded into a fan-like form. The electrodes, which are mounted in front of the board and below the transformer, consist of an inner metallic sheet, attached to a separating sheet of glass, and metallic gauze.—B. N.

Galvanic cell. C. F. G. A. Heil. First Addition, dated July 3, 1908 (under Int. Conv., June 11, 1908), to Fr. Pat. 392,429, July 1, 1908 (this J., 1909, 28).

THE mercury compounds used in the composition of the galvanic cell may be partly replaced by manganese dioxide.

The following is given as a suitable mixture—30 parts of manganese dioxide, 20 parts of mercury sulphate, 3 parts of mercury oxide, and 14 parts of graphite.—O. F. H.

Galvanic cell which becomes active on warming. J. Spiliotopol. Ger. Pat. 205,089, July 9, 1905.

THE cell has a tin cathode and a carbon anode, with chromium chloride solution as electrolyte, and a mixture of amorphous carbon, graphite, and manganous chloride, saturated with water, as depolariser. On warming, hydrochloric acid is produced by the action of water on the manganous chloride, manganese monoxide being also formed. In presence of water, hydrochloric acid interacts with both manganous chloride and manganese monoxide, with production of hydrated manganese peroxide and chlorine; there are thus two depolarising agents available.—A. S.

Electrodes containing powdered metals; Manufacture of —. C. Cornaro. Fr. Pat. 393,311, June 26, 1908. Under Int. Conv., June 27, 1907.

ELECTRODES of large radiating surface and very high specific resistance are made by preparing an intimate mixture of carbon, finely divided metal, such as aluminium or nickel, and metallic oxides or salts, such as oxides of magnesium, calcium, or manganese. The mixture is made into a paste with a solution of dextrin or other binding agent and pressed into plates or other forms under a pressure of about 200 atmospheres, the pressure being regulated to give the required specific resistance. The plates so formed are then heated to drive off the water and decompose the dextrin, and when cold submitted to a pressure equal to that previously employed.—O. F. H.

Conducting material; Composition and manufacture of a — of high electrical resistance. W. A. Phillips and F. R. Bacon. Fr. Pat. 393,430, Aug. 18, 1908.

THE conducting material consists of a non-conducting, fire-proof base such as clay, mixed with Portland cement or other calcareous binding agent, and which may be strengthened by inserting in it metallic foil or wire; and of one or more conducting substances, especially sulphites of iron and lead, or other compounds, e.g., oxides, arsenites, phosphates, etc., of these or other metals. The electrical resistance of lead sulphite increases with increasing temperature, whilst that of iron sulphite decreases, so that various effects may be obtained. The non-conducting base may be heated by itself and then immersed in a solution of the conducting substances; or the materials may be mixed together in the solid state; or the metallic compounds may be volatilised, and condensed drop by drop on the non-conducting material, by which they are absorbed in degree dependent on the proportion of calcareous material present. The mixed materials are burnt, and are suitable for constructing rheostats, for resistances for heating purposes, etc.—A. G. L.

Organic products; Process for the oxidation and reduction of — by electrolysis. H. Chaumat. Fr. Pat. 393,561, Oct. 29, 1907.

THE organic substance is intimately mixed with a conducting powder, such as graphite, on which the liberated oxygen and hydrogen are without action. The mixture is made into an agglomerated form, or simply piled up around a conductor, such as carbon, which constitutes the electrode, and which is bound to the negative pole for reduction and to the positive pole for oxidation.—B. N.

(B).—ELECTRO-METALLURGY.

Aluminium; Use of aluminium silicates in the manufacture of —. M. Moldenhauer. Metallurgie, 1909, 6, 14—19.

AFTER discussing various methods which have been proposed for obtaining aluminium from aluminium silicates (clay), the author describes experiments made by himself, which show that pure alumina can be prepared from clay by two distinct operations in the electric furnace, a high-grade ferrosilicon being obtained as by-product. In the first stage, calcined clay is heated with low-grade ferrosilicon and coke in an electric resistance furnace; the products obtained are carbon monoxide, ferrosilicon rich in silicon, and fused alumina containing some silica and a little iron oxide. The impure alumina is heated in a second similar furnace with iron oxide (haematite) and coke; the products in this case are carbon monoxide, low-grade ferrosilicon, and pure alumina; the latter in admixture with cryolite is then electrolysed as usual and the ferrosilicon returned to the first furnace. As regards the cryolite, its melting-point was found to be 975° C. Addition of alumina lowers the melting-point until a minimum is reached at 880° for 20 per cent. of alumina. Cryolite containing 20—25 per cent. of alumina is saturated with the latter; if more alumina is added the mixture rapidly becomes stiff.—A. G. L.

Zinc coatings; Production of — electrolytically. C. Richter. Elektrochem. Zeits., 1908, 15, 194—198. Chem. Zentr., 1909, 1, 321—322.

IT is stated that lustrous coatings of zinc can be obtained electrolytically, at the ordinary temperature, with a current of 1—1.5 amperes per sq. dem., and 1.135—1.8 volts, from a bath containing 140.23 grms. of crystallised zinc sulphate, 42.59 grms. of ammonium sulphate, and 1.274 grms. of sulphuric acid per litre. The composition of the bath is kept constant by the addition, during the electrolysis, of a solution consisting of 1 gm. of sulphuric acid, 0.889 gm. of ammonium sulphate, and 20.882 grms. of water. The satisfactory condition of the zinc coating is attributed to its being deposited as the result of a secondary reaction at the cathode. According to this view, the ammonium sulphate is first dissociated, with liberation of ammonium ions at the cathode, and solution of zinc as sulphate from the anode. The zinc sulphate forms a double sulphate with the ammonium sulphate, and this interacts with the ammonium ions to form ammonium sulphate with separation of metallic zinc.—A. S.

PATENTS.

Nickel; Removing electrolytic — or other metallic coating of metallic surfaces. A. Levy, Paris. Eng. Pat. 13,666, June 27, 1908.

THE articles are suspended on the positive pole, in a bath containing an electrolyte of sulphuric acid (48° to 52° B.) with a cathode of iron, aluminium, lead, or the like, or an electrolyte of "monohydrated nitric acid," the cathode, in the latter case, consisting of iron or aluminium. Instead of leaving the articles to be treated on the positive pole during the whole of the operation,

the current is reversed several times during the action, by means of a "reverser" if continuous current is used, or by the employment of an alternating current.—B. N.

Nickel from silicious ores; Process of obtaining —. E. F. Price, Niagara Falls, N.Y., Assignor to Central Trust Co., New York. U.S. Pats. 909,666 and 909,667, Jan. 12, 1909.

FERRO-NICKEL is electrically smelted from a silicious ore of nickel and iron mixed with carbon, either by surrounding an electric arc with a considerable body of the charge sufficient to protect the electrodes from oxidation, or else by passing an electric current through the charge functioning in this case as resistance material. The molten ferro-nickel produced is treated with air and an acid flux to remove iron, and the resulting high-grade nickel product is treated with a metallic deoxidising agent.—A. G. L.

Slimes; Treating electrolytic — for the recovery of metals. A. J. McNab, Assignor to W. H. Aldridge, Trail, British Columbia. U.S. Pat. 908,603, Jan. 5, 1909.

THE slime is treated with an alkali sulphide in order to convert metals, such as arsenic and antimony, into soluble sulphides, these being separated in solution from the insoluble sulphides, such as silver sulphide. Antimony is removed from the solution by electrolysis, and arsenic subsequently by crystallisation. The residue of insoluble sulphides is roasted, and the silver sulphate, which is formed, is separated by solution, the metallic silver being afterwards precipitated by a suitable reagent.—B. N.

Tungsten; Process for making alloys of — and of other similar and difficultly fusible metals. Siemens and Halske A.-G. Fr. Pat. 393,595, Aug. 22, 1908. Under Int. Conv., Sept. 14 and 26, and Dec. 9, 1907.

DUCTILE alloys of tungsten, nickel, and other metals are claimed, containing at least 60 per cent. of tungsten and at least 1 per cent. of nickel, especially an alloy containing 85–90 per cent. of tungsten and 15–10 per cent. of nickel, in which a part of the tungsten may be replaced by molybdenum or similar metal, and a part (up to 5 per cent.) of the nickel by iron. The ductile alloys are obtained by mixing finely-divided tungsten and nickel, or their oxides, especially the "colloidal" tungstic acid claimed in Fr. Pat. 378,743 of 1907 (this J., 1907, 1192), with a binding agent such as paraffin wax, forming the mass into thin rods, drying, and heating the rods electrically in tubes through which a current of hydrogen is led. The temperature is raised very gradually to 1100° C., where it is kept for 1 hour, after which it is raised for 5 minutes to about 1400° C. The metallic rods obtained are then reheated, in the same way, at 1400–1500° C., depending on their composition, to give them the required ductility. The rods are next worked or drawn into very thin wire suitable for electric incandescent filaments. This wire is then freed from nickel by placing it in a vacuum and heating it by passing an electric current through the wire, the nickel volatilising during this process.—A. G. L.

Sodium; Electrolytic manufacture of —. Soc. d'Electrochimie and P. L. Hulin. Fr. Pat. 393,706, Nov. 2, 1907.

FUSED caustic soda is electrolysed in an apparatus provided with a removable cathode, formed of a number of copper rods suitably spaced apart. The anodes consist of sheets of iron or steel, either in the form of a cylinder, with the cathode rods arranged concentrically within the cylinder, or as flat plates with rows of cathode rods parallel to the plates. Above the space between the electrodes is arranged a separator, in the form of a frame or hoop, partially immersed in the caustic soda, and serving to collect the metal. An alternative form is described, consisting of a removable tray with the edge turned downwards, the metal being collected within the tray and protected from contact with the air. The metal is withdrawn from a narrow tube mounted on the tray. The action diminishes considerably after a time, but the surface of the cathode may be revived by periodical

washing. A sheet-iron conductor is arranged below the electrolytic bath, and serves to heat the latter, the conductor being brought to a red heat by a suitable current.—B. N.

Ferrosilicon; Process of treating acid slags or silicious iron ores, with a view to their use for the manufacture of — in the electric furnace. V. C. Bertolus. Fr. Pat. 393,818, Aug. 31, 1908.

ACID slags from a Siemens-Martin or Bessemer furnace, silicious iron ores, etc., are granulated or powdered, mixed with a reducing agent, e.g., coke or charcoal, and with silica, and formed into briquettes with the aid of tar, sodium silicate, etc. If phosphorus is present, a small quantity of sodium chloride, or other chloride, is added to eliminate it. The briquettes are then heated in an electric furnace to produce ferrosilicon.—A. G. L.

Tin plating; Electrolytic —. J. Feith. Ger. Pat. 295,051, March 13, 1907.

IT is stated that by addition of a small quantity of a cadmium salt to the bath, strong adherent coatings are produced, and hollows of 40 cm. depth are efficiently coated without the use of special anodes. A suitable electrolyte consists of 30–60 grms. of cadmium chloride and 1–2 kilos. of a tin salt per 100 litres.—A. S.

XII.—FATTY OILS, FATS, WAXES, AND SOAPS.

Fats; Hydrolysis of — by means of pancreas. E. Baur. Z. angew. Chem., 1909, 22, 97–100.

IN Lewkowitzsch's experiments with lipase from pig's liver (this J., 1903, 67) the small extent of hydrolysis was attributed to deficient emulsification. (Compare however Lewkowitzsch, this J., 1903, 1094). Subsequently Fokin (this J., 1904, 1152) succeeded in hydrolysing almond oil to the extent of 82 per cent. in 7 days by means of pancreatic juice with the addition of small amounts of alkali during the reaction. He considered the method unsuitable, however, for technical purposes. The author has found that an addition of Turkey-red oil to the mixture of fat, water, and pancreas produces an excellent emulsion, but that such an addition is unnecessary if the mixture be maintained at a very slight but definite degree of alkalinity. For use on a large scale a dry preparation of the pancreatic glands is required. The fresh pancreas of swine is freed from fat and connective tissue, then finely cut up by machinery, and allowed to stand for a day or more in contact with twice its amount of alcohol. The mass is now strained and pressed, and the residue once more finely divided in the machine and again treated with alcohol. The united turbid alcoholic extracts are treated with sufficient ether to precipitate the suspended particles of the glands, and the deposit is washed with ether, and spread in a thin layer on filter paper to dry. As thus obtained it is a light, friable, odourless, and tasteless powder, which retains for many months its lipolytic power intact. The residual mass from the alcoholic extractions may be treated with ether and dried in the air, and used as a preparation of second quality. Its action is slower than that of the purer preparation. The pancreas of oxen may also be used in the manufacture of a durable preparation. It has the same lipolytic power as the preparation from swine, but has the drawback that the fibres of connective tissue are larger. In using these preparations they are first formed into a homogeneous paste with water, which is then mixed with the fat to

be hydrolysed in the proportion of about 5 per cent. When the oil or melted fat is mechanically stirred with the paste, emulsification soon occurs. After 30 minutes to 1 hour, 5 per cent. sodium carbonate solution is gradually added, the addition being so regulated that the emulsion when tested with red and blue litmus paper always produces a violet stain on each. After about 1 to 2 hours the requisite amount of alkali (corresponding to about 25 per cent. of the fatty acids) will have been added, and the mass will usually have become too thick from the separation of fatty acids for the stirring to be continued. The mass is then left to itself. After 5 hours from 60 to 80 per cent. of the fat will usually have been hydrolysed, and the hydrolysis will be complete in 1 to 4 days. In one of the typical experiments quoted, 100 grms. of ox-tallow were melted and mixed at 40° C. with 6 grms. of pancreas powder made into a paste with 60 c.c. of water. The mass was stirred for an hour at 35° C., after which 80 c.c. of $N/1$ sodium carbonate solution were added little by little. After 5 hours 66 per cent. of the fat had been hydrolysed, and the reaction was complete in 4 days. In place of such preparations, freshly-obtained pancreas may be employed, after being finely divided and ground up in a mortar with the requisite quantity of water. It has the drawback, however, that the fibres may interfere with the stirring apparatus during the hydrolysis. In the author's opinion pancreatic hydrolysis of fats might be used with advantage in the stearine industry. It has the advantage over hydrolysis with castor seeds that the reaction is complete, whereas with the latter only about 90 per cent. of the fatty acids are liberated. On the other hand, castor seeds are cheaper and more easily dealt with than the pancreatic glands of animals.—C. A. M.

Fish oils: Bromine addition-compounds of — H. Bull and J. C. F. Johannesen. *Chem.-Zeit.*, 1909, **33**, 73–74.

HEUSER and Mitchell (this J., 1899, 77) described methods of differentiating the oils of marine animals by means of the amounts of insoluble bromides to be obtained from the oils themselves and their fatty acids. As the authors have met with difficulties in the filtration of the precipitates yielded by the glycerides, they have worked out conditions for obtaining concordant results with the fatty acids. The following method is that chosen as the most satisfactory of those tried and described in the paper:—From 0.9 to 1.1 grm. of the fatty acids is dissolved in 25 c.c. of a mixture of 100 c.c. of glacial acetic acid and 500 c.c. of anhydrous ether, and the flask (of about 75 c.c. capacity) closed and immersed in ice-water. Bromine is now slowly added, drop by drop, from a burette, with constant shaking, and after the addition of 0.5 c.c. the flask is left for some minutes in the ice-water, and then allowed to stand for 3 hours at the ordinary temperature. The precipitate is collected in a weighed Soxhlet's filter-tube containing asbestos, the filtration being accelerated by means of a filter-pump. The flask is rinsed out with 3 portions of 5 c.c. of the mixture of ether and acetic acid, and the precipitate finally washed twice with the same quantities of solvent, after which the tube is dried for 2 hours at 100° C. and weighed. The amounts of bromide thus obtained in closely concordant determinations from the fatty acids from 10 samples of commercial cod liver oil ranged from 27.40 to 37.77 per cent.—C. A. M.

Cottonseed oil: "Denaturing" of — G. Winterfeld. *Chem.-Zeit.*, 1909, **33**, 37–38.

PRIOR to 1906 the German Customs regulations prescribed that fatty oils intended for technical purposes should be "denatured" by, *inter alia*, the addition of 3 kilos. of potassium hydroxide solution of sp. gr. 1.29 or of sodium hydroxide solution of sp. gr. 1.34 to 100 kilos. of oil. As it was found that 80 to 90 per cent. of such oil could be recovered and used for food, the use of sodium or potassium hydroxides for this purpose was prohibited. As the substances, such as rosenary oil, still permitted are more expensive than the alkali solutions, the author has made experiments to determine to what extent the

latter are effective. He shows that in the case of cottonseed oil containing 10 to 15 per cent. of potassium hydroxide solution of sp. gr. 1.32 or of sodium hydroxide solution of sp. gr. 1.34, it is possible to recover from 60 to 80 per cent. of the oil, which, though of inferior quality, might still be used for food purposes; but that it is questionable whether the treatment would be profitable. In his opinion cottonseed oil would be effectively "denatured" by the addition of the above-named proportion of alkali.—C. A. M.

Oil from "Carapa Guyanensis" (Carapa Procerca, DC.). J. Lewkowitsch. *Analyst*, 1909, **34**, 10–11.

THE oil to which the following figures relate was obtained from seeds sent from Sierra Leone as *Carapa guyanensis*, Aubl., but they were probably derived from *Carapa procerca*, DC., of which *C. guyanensis* and *C. guineensis* are synonyms (see this J., 1908, 578). The seeds examined consisted of:—Good kernels, 35.5 per cent.; bad (mouldy) kernels, 27.0 per cent.; shells, 37.5 per cent. The sound kernels yielded by extraction with ether, 57.26 per cent. of oil, having an iodine value of 75.09. The oils obtained from the kernels by cold and hot pressing gave the following figures on analysis:—

	Cold-pressed oil.	Hot-pressed oil.
Yield, per cent.	24.0	27.0
Sp. gr. at 40°/40° C.	0.9170	0.9174
Sp. gr. at 15.5°/15.5° C.	0.9272	0.9327
Solidification point	12° C.	14° C.
Melting point	15°–36° C.	15°–48° C.
Saponification value	197.1	196.4
Iodine value	75.07	71.25
Reichert-Meissl value	3.53	3.14
Unsaponifiable matter, per cent.	1.51	2.04
<i>Insoluble fatty acids.</i>		
Fatty acids + unsap. matter, per cent.	95.13	92.66
Solidifying point (titer test)	35–45° C.	36–15° C.
Neutralisation value	192.4	192.0
Mean mol. wt. of fatty acids ...	291.5	292.1
"Liquid fatty acids" (yielding ether-soluble lead salts), per cent.	65.9	63.4
"Solid fatty acids" (yielding ether-insol. lead salts), per cent.	34.1	36.54
Iodine value of "liquid acids" ...	107.4	108.0
Iodine value of "solid acids" ...	16.6	17.9

The oil did not contain any optically active substances.—W. P. S.

Turkey red oils or similar fatty preparations; Behaviour of mixtures of — with glycerides and especially tournant oils and their substitution products. F. Erban. *Z. angew. Chem.*, 1909, **22**, 55–69.

FROM experiments described in detail the author concludes that neither free oleic acid nor ricinoleic acid has a solvent action upon glycerides, but that higher hydroxy-acids render Schmitz's "Oeläther" (a commercial product probably consisting of the glyceride of a hydroxy-acid) soluble, and have probably an analogous effect upon other glycerides of hydroxy-acids. With regard to Turkey-red oils it appears that unwashed products of a low degree of sulphonation (provided they do not contain too much unaltered castor oil) are capable under all conditions of dissolving certain glycerides, such as are present in many tournant oils and esters of oxidised oils. Oils of an intermediate degree of sulphonation have this property so long as they are not treated with excess of alkali, whilst highly-sulphonated oils have a solvent action in the fresh unwashed condition, but lose it partially or completely after washing and neutralisation. This characteristic appears therefore, to stand in direct relationship to the proportion of glycerides remaining in a Turkey-red oil, and to be lost when the glycerides are decomposed with the formation of free sulphonated fatty acids. Saponification cannot be the cause of solution of glycerides still present, since in the experiments described, clear solutions were, as a rule, obtained only so long as the reaction was still slightly acid, whilst on the other hand

even a small excess of alkali had an injurious effect when the product was neutralised and allowed to stand. The solubility of tourment oils does not depend upon the proportion of free acids they contain, since mixtures of 73 per cent. of neutral fat with 27 per cent. of oleic acid only yield emulsions, and tourment oils are met with in commerce, which have higher and lower acidities than this and are also insoluble. It is probable that these differences may be found to be due to the varying proportion of diglycerides in the oils.—C. A. M.

Soap solutions; Action of carbon dioxide on —. G. Fendler and O. Kuhn. *Z. angew. Chem.*, 1909, 22, 107—108.

CARBON dioxide can effect the dissociation of soap solutions even when they are strongly alkaline and contain a large amount of alcohol. The proportion of fatty acids liberated varies considerably with the nature of the fat from which the soap was derived. Thus in comparative experiments, 5 grms. of fat or oil were saponified with 10 c.c. of alcoholic potassium hydroxide (20 grms. per 100 c.c. of 70 per cent. alcohol), and the soap dissolved in alcohol and water, so that the final solution (100 c.c.) contained 40 per cent. of alcohol. Each solution was treated for an hour with a fairly rapid current of carbon dioxide previously passed through 40 per cent. alcohol. It was found that the soap solutions from lard, butter, tallow, coconut oil, and arachis oil became more or less turbid, whilst olive and almond oil soap solutions remained clear. The following amounts of fatty acids were extracted with petroleum spirit from the respective solutions:—Lard, 9.94; butter fat, 8.00; tallow, 7.61; coconut oil, 12.30; olive oil, 13.79; arachis oil, 15.34; almond oil, 14.50; and linseed oil, 14.32 per cent. In experiments with butter fat soap solution in which the treatment with carbon dioxide and extraction of the fatty acids was repeated 12 times, it was found that the acids of high molecular weight were the first to be liberated.

PATENT.

Rosin soap and the like; Apparatus and method for the manufacture of —. A. W. Carmichael, Savannah, Ga. U.S. Pats. 909,958 and 909,951, Jan. 5, 1909.

(1). THE apparatus consists of a vessel provided with a steam-jacket; a rotating "foam-beater" or stirrer is fitted inside and at the top of the vessel, and means are provided for withdrawing the liquid from the bottom of the vessel and discharging it into the space above the stirrer. (2). The process consists in heating a saponified solution of rosin in the vessel described above; the stirrer breaks down the foam rising at the surface of the solution and, during the heating, the solution is pumped from the bottom of the vessel and discharged into the latter above the stirrer.—W. P. S.

XIII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, &c.

PATENTS.

Waterproofing paint for Portland cement buildings. (1) and (3), and *waterproofing fibres and fabrics* (2). T. A. Edison, Orange, N.J., Assignor to North Jersey Paint Co., Stewartsville, N.J. U.S. Pats. 909,167—909,169, Jan. 12, 1909.

(1). The waterproof paint consists of petroleum residue known as "B.S." dissolved in a suitable solvent, to which boiled linseed oil and a coloured pigment may be added. (2). Fibres and fabrics are impregnated with that portion of a petroleum residue known as "B.S." which is soluble in benzene and has been freed from the insoluble portion. (3). The waterproofing paint consists of that portion of

a petroleum residue known as "B.S." which is soluble in benzene, dissolved in benzene and freed from the insoluble portion and from a part of the solvent.—A. G. L.

Pigments by electrolysis; Art of producing —. U.S. Pat. 906,102. See XI.1.

(B).—RESINS, VARNISHES.

Colophony; A colour reaction of —. P. Foerster. *Ann. Chim. analyt.*, 1909, 14, 14—17.

HALPHEN'S reagent for the detection of traces of rosin oil in mineral oil (*Ann. Chim. analyt.*, 1903, 8, 9) is also capable of detecting traces of colophony. It consists of:—(A). 1 part by volume of phenol dissolved in 2 parts of carbon tetrachloride; and (B). 1 part of bromine in 4 parts of carbon tetrachloride. On treating a little powdered colophony in a basin with 2 c.c. of solution A, and bringing the liquid close to the solution B, a bright blue coloration, subsequently changing to violet, is produced at the place where the vapours of bromine impinge. The reaction differs from that given by rosin oil, for in that case the first coloration is violet. In applying the reaction to the detection of colophony in other substances, it is usually necessary to separate the colophony beforehand. In the case of soap a small quantity of the sample is dissolved in 80 per cent. alcohol, the solution treated with calcium chloride and filtered, and the filtrate slightly acidified with hydrochloric acid and evaporated. The residue is then tested with Halphen's reagent. In testing shellac, 2 grms. of the substance are pulverised with sand, the mixture shaken for 5 to 10 minutes with 10 to 15 c.c. of ether, the liquid filtered and evaporated, and the residue tested with the reagent. *Jalap resin*:—From 0.2 to 0.5 gm. of the resin is treated with a few c.c. of petroleum spirit, the liquid filtered after a few moments, the filtrate evaporated, and the residue tested. If the jalap contained 1 to 2 per cent. of colophony a distinct blue coloration is obtained. For the detection of traces of gnaiaecum resin, a little of the jalap is dissolved in a few drops of acetic acid, or, better, acetic anhydride, and the solution subjected to the action of the bromine vapours from the solution B. In the presence of gnaiaecum resin a bright blue coloration, changed to green by excess of bromine, is obtained.

Pine oil, pine tar oil, or wood tar oil; Purification of —. L. Ahlers. *Ger. Pat.* 204,391, June 30, 1906.

THE oil, which has been previously treated with alkali and washed with water, is heated with zinc dust in a still provided with a reflux condenser. For example, 1000 kilos. of pine tar oil are heated with 10 kilos. of zinc dust for 1 hour at about 100° C. by means of indirect steam. After cooling, the oil is separated and is washed, in a vessel provided with an agitator, with warm soft water, until the latter is no longer coloured yellow on addition of alkali. The oil is finally distilled with steam.—A. S.

Shellac; Decolorisation of —. F. Daum. *Ger. Pat.* 205,172, March 1, 1907.

THE shellac is treated with an aqueous emulsion of fats, and the latter are subsequently removed by extraction or by other suitable means. For instance, 6 kilos. of coconut oil or other fat are formed into an emulsion with 300 litres of hot water, 100 kilos. of stick-lac or dark-coloured shellac are added, and the whole is agitated and boiled. The shellac is then removed, and after

cooling, is dissolved in alcohol, the dirt and excess of fat being separated by filtering the solution or allowing it to settle.—A. S.

Linoleum substitute; Process and apparatus for making a — from fibrous materials. N. Rief. Fr. Pat. 393,868, Sept. 2, 1908.

THE process relates to the manufacture of a material similar to linoleum, the substances used being cellulose, cork, peat, etc., and vulcanised oil. The fibrous material is passed between rollers provided with helical cutters, by means of which it is finely divided and is then delivered in the form of a sheet into a vessel where both surfaces of the sheet are sprayed with the agglutinating solution. Arriving at the bottom of the vessel, the treated material is forced, by means of a screw, between rollers and then through heated channels, where the vulcanisation is completed. The agglutinating solution is prepared by heating oil, or a mixture of oil and pitch, to a temperature of 150° C. for 15 minutes, during which time a current of air is blown through it; melted sulphur containing a catalytic agent, such as resin or metals in a finely divided state, is then added rapidly, and the mixture is cooled before vulcanisation is completed. Colouring matters and basic substances may be added and the liquid is then sprayed on the fibrous material as described. A particularly durable linoleum is obtained if the fibrous material be also sprayed, at the same time that it receives the agglutinating liquid, with small quantities of sulphur chloride or nitric acid.—W. P. S.

Linoleum substitute; Preparation of a —. J. Michael, Ger. Pat. 205,770, Aug. 31, 1907.

A FATTY oil is heated for a short time and is then vulcanised by treatment with a molten mixture of rosin and sulphur, air being blown into the mass during the operation. The vulcanised oil, before it sets, is then distributed, in a fine state of division, over the fabric which is to form the foundation of the material. If a specially hard material is desired, small quantities of a vulcanising agent, capable of being spread or finely divided, e.g., sulphur chloride, are mixed with the vulcanised oil as it is being distributed over the fabric, and the material is subsequently passed between heated rollers.—A. S.

XIV.—TANNING, LEATHER, GLUE, SIZE.

Cutch trade in Burma; A note on the present position and future prospects of the —. R. S. Troup. Indian Forest Records, 1908, 1, [III].

BURMA cutch is obtained by extracting chips of the heartwood of *Acacia catechu*, Willd. with water, then

boiling down the extract to a syrup and allowing it to set. Its valuable constituents are a tannin and catechin. The quantity and the value of the cutch exported from Burma have seriously decreased during recent years. The following reasons are assigned for this decline:—(1). Cutch was formerly employed to a large extent for dyeing, but it has been almost entirely replaced for this purpose by artificial dyestuffs and it is now chiefly employed for preserving fishing nets and sails. (2). Inferior qualities of Burma cutch have been largely displaced from the market by the cheaper mangrove cutch, an extract from the barks of mangroves, the chief of which are *Ceriops Candolleana* and *Rhizophora spp.* Mangrove cutch does not answer the general tests for cutches. It is quite soluble in cold water and contains no catechin. (3). Adulteration of cutch was freely practised in past years and did permanent harm to the trade. The quality now manufactured is rarely adulterated, its chief fault being that it occasionally contains too much moisture.

Cutch exported from Burma during the years 1894–95 to 1906–07.

Sole leathers; Colouring matters in connection with —. H. G. Crockett. J. Soc. Dyers and Color., 1909, 25, 8–10.

THE leather derives its colour from the natural colouring matters contained in the tanning material and the aim is to imitate the colour produced by oak bark. Where other tanning materials, such as American hemlock (which produces a pink to red colour), have been employed, this is not always easy, and manufacturers of tanning extracts often sell their products under guarantee that these are decolorised by certain methods. The colour of the leather is preserved during drying by the exercise of great care, thus avoiding dark edges and stains; the finished huts are often finally coloured by rubbing pigment colours ("chrome yellow" or ochre mixed with size and oil) into the grain, wiping, brushing, and finally rolling under a heavy brass roller. Annatto or aniline dyestuffs may also be used to level the shade and cover defects. "Surface" finished leather however is always detected by cutting, the edges of the cut being different in colour to the surface. Shoemakers have also learnt how to colour the shoe sole and waist, so that it shall appear to be of well-tanned bark leather. Saffron, dragon's blood, cochineal, annatto, chrysoidine, Bismarck brown, logwood, and nigrosine have all been recommended and used.—F. M.

XV.—MANURES, &c.

Nitrification and denitrification in soils. St. v. Lazarewski. N. Jahrb. f. Mineral., 1908, II., 186. Chem. Zentr., 1909, 1, 309—310.

NITRIFYING bacteria occur most abundantly in the top layers of the soil, down to a depth of 10 cm.; at a depth of 50 cm., they are very rare. Their existence depends upon the presence of oxygen and humus. After growing certain plants on the soil, the number of nitrifying bacteria increases, even in the deeper layers. The most favourable temperature for nitrification in the soil is about 25°—27° C., or 10° lower than is the case in artificial nutrient media. The soluble organic substances present, in small quantities, in the soil have no injurious effect on nitrification, but probably accelerate it, since in pure cultures, dextrose has a favourable effect when added in quantities up to 1 per cent., and is injurious only in larger amounts. Denitrifying bacteria are present in large quantities in the upper layers of the soil; their distribution with regard to depth is quite irregular, and they frequently occur abundantly even at depths greater than 1 m. In mixed cultures the optimum temperatures for nitrifying and denitrifying bacteria appear to be nearly identical.—A. S.

Nitrolime [crude calcium cyanamide]; Decomposition of — in the soil. (1) F. Löhms and R. Moll. Zentrbl. Bakter. u. Parasitenk., 1908, II. Abt., 22, 254—281; (2) H. Kappen, *ibid.*, 281—298. Chem. Zentr., 1909, 1, 310—311.

XVI.—SUGAR, STARCH, GUM, &c.

Starch; Formation of crystalline substances (polysaccharides), having no reducing action on Fehling's solution, from — by the action of microbes. F. Schardinger. Zentrbl. Bakter. u. Parasitenk., 1908, II. Abt., 22, 98—103. Chem. Zentr., 1909, 1, 68—69.

AQUEOUS pastes of wheat, rice, maize, potato, and arrowroot starches, containing some sodium chloride and 1 part of ammonium phosphate and 0.25 part of magnesium sulphate per 1000, were inoculated with well washed potato cultures of *Bac. macerans* (see Zentrbl. Bakter. u. Parasitenk., II. Abt., 14, 772; 19, 161) at 40° C., and then kept at 45° C. After 3—4 days the potato and arrowroot starches were almost completely dissolved; in the other cases, solution proceeded more slowly; in the early stages of the action, an odour of acetone was perceptible. The solutions produced contained one or more crystallisable compounds. The hexagonal crystals obtained from the solution yielded by wheat starch, when treated with iodine under the microscope, were seen to disappear, their place being taken by greyish-green to greyish-yellow bundles of needles; when two adjacent bundles of needles crossed each other, the region of contact appeared blue. The hexagonal crystals also took up water, yielding prisms. The best yield of the crystalline substance was obtained from wheat, but it was most easily obtained pure from arrowroot. Its content of water of crystallisation ranged from 14.17—14.76 per cent., according to its origin; its specific rotatory power in 1 per cent. aqueous solution at 20° C. was +136° to +138.4°; its composition was probably represented by the formula, $C_6H_{10}O_5 + 3H_2O$. The author names it "crystallised amyloextrin." From the mother-liquor from wheat amyloextrin, lancet-shaped needles of a second substance were isolated. This was named "crystallised amylose"; its specific rotatory power in 1 per cent. solution at 20° C. was +127.4°. Neither of the substances in 1 per cent. aqueous solution reduced Fehling's solution, nor were they fermented by yeast. Iodine produced a precipitate in a solution of the amyloextrin, but not in a solution containing equal proportions of the amyloextrin and amylose.—A. S.

PATENTS.

Sugar and ethyl alcohol; Process for the industrial production of —. J. B. Gailhat. Fr. Pat. 393,716, Aug. 28, 1908.

CLADI is made for the use of the following materials for the production of sugar and alcohol:—pea pods and stalks, maize stalks, asparagus stalks, red clover, etc. It is essential that these materials be used while green.—W. P. S.

Gum tragacanth; Manufacture of —. C. V. Greenwood. Liverpool. Eng. Pat. 569, Jan. 9, 1908.

GUM tragacanth as made by the process described in Eng. Pats. 24,877 of 1894 and 10,822 of 1905 (this J., 1906, 944) may be rendered more soluble by the addition, during the course of manufacture, of formic acid. Other organic acids, whether added or formed in the gum by the action of enzymes, may be used. When the gum is intended for edible purposes, it is preferable to add tartaric or citric acid, or a suitable enzyme. About 1 lb. of formic acid may be added to each ton of the gum. The treated gum may be concentrated either with or without the addition of waxes, resins, gums, or starchy material, etc.—W. P. S.

Extracting sugar beets, etc. Ger. Pat. 205,253. See XIV.

XVII.—BREWING, WINES, SPIRITS, &c.

Diastatic processes; Surface influences in —. F. Emmlander. Z.-Chem. u. Ind. Kolloide, 1908, 2, 308—310.

COMPARATIVE mashing experiments were made with 50 grms. of malt: (1), in the usual manner; (2), with a thin layer of toluene covering the mixture; and (3), with a covering layer of vaseline oil. In the two latter cases,

the extract contained more dextrin but less maltose and albumin than in the first case; also the ratio of non-sugar to sugar in the extract was greater when covering layers were used. Continuous stirring during the mashing process had no considerable effect on the proportions of maltose, dextrin, and albumin in the extract, but contrary to expectation, the final degree of attenuation was higher with the wort prepared in the usual manner than when the mashing was effected with continuous stirring. Comparative experiments were also made as to the influence of the surface of the containing vessel, the results being shown in the following table:—In (1) the mashing was effected in the usual manner; in (2) the mashing beaker was coated with shellac; in (3) the mixture was covered with a layer of paraffin oil.

	(1)	(2)	(3)

Colour malt in the brewery: Methods of applying — G. Jakob and E. Rausch. *Woch. für Brau.*, 1909, 26, 1—6.

IN preparing dark beers of the Munich type, the colour malt may either be mixed in the mash tun or else employed for brewing a special black beer or concentrated beer colouring, which is then blended with the bulk either before or after fermentation. The authors prefer the first mode of application, but if the colour malt be subjected to the usual decoction process, or even if it be added to the mash tun after running off the wort and before sparging, the temperature at which extraction takes place is so high that acrid matters, which injuriously affect the flavour of the beer, are derived from the husk. On the other hand, if the colour malt be infused cold, there is a deficiency in the yield of extract of about 6 per cent. and a deficiency in the colouring power of about 25 per cent., as compared with extraction at 100° C. This deficiency would involve an increased consumption of colour malt amounting to 33 per cent. when working by cold infusion, but since the proportion of colour malt employed is generally only 0.8—1.0 per cent. of the total malt, the improvement in flavour obtained by cold extraction compensates for the increased cost; moreover a wort of lower gravity may be brewed. The colour malt should be very finely ground and mixed with cold water in a separate small mash-tun. After infusing for 15 minutes, the coloured extract should be run off clear into the main mash tun and the residue should be extracted several times with cold water. In this way the soluble carbohydrates of the colour malt are fully saccharified without the grains being heated with the rest of the mash. Several methods are available for the preparation of special colouring beers or beer-colourings; six processes are mentioned by the authors, who select Schramm's process as the simplest and most convenient. This consists in infusing the colour malt with cold water and clarifying the extract by filtration, finally concentrating it to the consistency of caramel. An extract so prepared has no acrid flavour and possesses the property of imparting a yellowish colour to the foam of the beer.—J. E. B.

Extract: Increase of the — [of malt] by previous doughing-in of the grist. J. J. van Hest. *Z. ges. Brauw.*, 1909, 32, 30—31.

THE author criticises Bleisch's statement (this J., 1909, 34) that the increase of extract obtained from malt by previous doughing-in of the malt at a temperature of 1—25° C. (34—77° F.) is an apparent and not a real increase. The principal cause of the increase is that at 34—77° F., starch, albumin, pentosans, colouring matters, mineral salts, etc., are attacked which would not be attacked at a mashing temperature of about 113° F., so that no increase in the extract is observed if the mash is allowed to stand for 1—10 hours at 113° F. The author shows that

doughing-in gives a greater yield of beer and that the reality of the increased extract is confirmed by estimation of the solid matter remaining in the grains.—T. H. P.

Digestive mashing. W. Windisch. *Woch. f. Brau.*, 1909, 26, 18—20.

THE author has had occasion to examine many beers prepared from worts obtained by Van Hest's process of digestive mashing, in which the malt is doughed-in at ordinary temperature and allowed to stand over-night before the mashing is proceeded with (see Bleisch, this J., 1909, 34). The method when applied to the preparation of pale beer worts frequently leads to the production of a foxy colour in the finished article which is very objectionable. Experiments were carried out to discover which part of the corn was responsible for this production of colour and it was found to be derived from the husk, as mashes in which only the meal and grits were doughed-in, the husks being added at the time of the mashing proper, gave wort of nearly the normal tint, whereas that yielded by the mixed grist was nearly twice as dark. The character of the beer is also frequently affected prejudicially, although this is by no means always so. The increase in yield of extract produced by doughing-in is greatest with under-modified malts and least with thoroughly modified material. (See preceding abstract.)—R. L. S.

Extract: Increased yield of — from malt by preliminary digestion of the grist. E. Moufang. *Woch. f. Brau.*, 1909, 26, 43.

THAT an increase in the extract yielded by a malt may be effected by digestion or doughing-in of the grist previous to mashing is quite feasible, such procedure resulting in: (1), mechanical actions due to thorough moistening of the grist; and (2), enzyme actions, by which the starch and, principally, the proteins are degraded; that such proteolytic action does take place is rendered probable by an observed alteration of the form in which the soluble nitrogen compounds appear in the final wort when the doughed-in grist has been allowed to stand for some hours previous to mashing. Experiment shows that the constituents thus dissolved are really in solution and remain so, the boiled wort from a doughed-in grist containing 0.2—0.4 per cent. more extract than when doughing-in is omitted. (See also this J., 1909, 34, and preceding abstracts.)

—T. H. P.

Yeast juice: Fractional precipitation of expressed — E. Buchner and F. Duchacek. *Biochem. Zeits.*, 1909, 15, 221—253.

IT has not yet been found possible to separate the enzymes, yeast zymase and lactacidase (this J., 1905, 246), concerned in the fermentation of sugar, and the name zymase may be used provisionally to denote the mixture of enzymes. But yeast juice contains another body, indispensable for sugar decomposition, the so-called co-enzyme (Harden and Young, this J., 1906, 490, 1111), which is dialysable and can withstand boiling. Since zymase and the co-enzyme may behave differently towards precipitants, the authors have now revised earlier work on the precipitation of the constituents of yeast juice. Preliminary experiments made to determine the fermenting power of the expressed juices used, and the regenerative power of the various boiled juices, showed, in confirmation of earlier results, that juice which has lost its fermenting power by exercise of this function, acquires it again on addition of boiled juice. If, however, the exhausted juice is left for some time after it has lost its fermenting power, it cannot be regenerated by addition of boiled juice: the boiled juice is more stable, being able to regenerate exhausted juice after it has been kept for more than three weeks. Active juice can be rendered more active by addition of boiled juice, which appears to indicate that active juice is often deficient in co-enzyme. In previous experiments on fractional precipitation, the expressed juice has generally been added to the precipitant, but the authors point out that a systematic separation of the constituents according to their solubility, cannot be thus effected, since the first portion of the juice comes in contact with a large excess of precipitant. They have

therefore generally added the precipitant (acetone, alcohol, or alcohol-ether) to the juice, with stirring. Acetone was found to be a better precipitant than alcohol-ether, and much better than absolute alcohol. In some cases, three fractions were obtained, and in others, only two, in order to lessen the time of contact between precipitate and precipitant. The first and second fractions, in all cases, showed only a slight fermenting power, the third generally showed none. Addition of boiled juice increased the activity of fractions 1 and 2, that of No. 1 generally to a greater extent. Hence, fraction 1 appears to be poorer in co-enzyme, which is thrown down more abundantly as the precipitant becomes more concentrated; a progressive increase of the phosphoric acid-content from fraction 1 to fraction 3, accords with this view. The fractions were found to increase the fermenting power of fresh expressed juice, and to regenerate exhausted juice; the second fraction had a greater regenerating power than the first, this also, probably being connected with the greater content of co-enzyme in the former. The fermenting power of a mixture of the three successive fractions was found to be only about one-third of that of the original juice; addition of the final mother liquor (freed from precipitant and concentrated) did not increase this activity. These results show that important constituents of the fermenting agent are destroyed during fractional precipitation. The co-enzyme is very sensitive to certain influences and it was found that the activity of the united fractions was considerably increased by addition of boiled juice (in one case, to five-sevenths of that of the original juice). If, instead of adding acetone to the juice, the latter is added to 10 volumes of acetone, the precipitate obtained, even though left in contact with the precipitant for an hour, has as great a fermenting power as the original juice; though the same amount of precipitate is obtained by adding 10 volumes of acetone to the juice, the activity of this precipitate is more or less destroyed. The authors conclude that when acetone is run, drop by drop, into the juice (and, generally, when the juice comes in contact with a small quantity of acetone), precipitates of high water-content are obtained, which rapidly suffer change, probably owing to mutual enzyme action; with the reverse process, the precipitate obtained has a low water-content and is more stable. Experiments in which juices of strong and weak activity were added to 10 volumes of acetone, showed that the yield of precipitate from the latter was only four-fifths of that obtained from the former; it may be that in juice of low fermenting power, the coagulable protein is already considerably decomposed, and the fermentation agent injured, by the proteolytic enzymes.—L. E.

Alcoholic fermentation: Influence of aëration on the volatile products of —. E. Kayser and A. Demolon. *Compt. rend.*, 1909, 148, 103—105. (See also this J., 1907, 1060.)

THE authors have previously called attention to the part played by the living yeast in the ageing of wine on the lees in contact with air. They have now studied the changes due to moderate aëration in a fermented liquid in presence of the yeast. The liquid was composed of an extract of malt culms, containing originally 15.7 per cent. of sugar. Two yeasts were studied, one a champagne wine yeast and the other a powerfully aerobic yeast from pineapples, and parallel fermentations were made: (a), in flasks with long necks, nearly full of liquid, (b), in flat, wide flasks only partially filled, so as to expose a large surface to the air. Analyses were then made after one and six months respectively. Comparing the results after one month, the effect of aëration on the composition of the "wine" was very marked. In the case of the wine yeast, the difference between the flask with small exposed surface and that with a large surface was shown mainly in the large production of aldehydes in the latter. In the case of the more powerfully oxidising pineapple yeast, the aldehydes were only moderately pronounced and the effect of the aëration was marked more especially by the production of volatile acids. In the second series, after six months, in the case of the wine yeast, the aldehydes had increased in the flask with restricted aëration, but had decreased in the flat, wide flask. In the case of the

pineapple yeast the alcohol had largely disappeared after six months, the aldehydes had totally disappeared, and the volatile acids had considerably decreased, particularly in the wide flask. In this case respiratory oxidation had been very active and the quantity of yeast had largely increased, some of the volatile acid being consumed and a portion being converted into esters, which had increased particularly in the flask with restricted aëration. In the case of wines, when the proportion of aldehydes increases during ageing, it is due to the fixation of these compounds, e.g., by the colouring matters, and their protection from secondary oxidation.—J. F. B.

Beer: Pasteurisation of —. P. Petit. *Woch. f. Brau.*, 1909, 26, 20—21.

DURING pasteurisation a portion of the carbon dioxide contained in the beer is liberated and not redissolved on cooling, so that an excess pressure within the bottle is produced. The breakage of bottles during pasteurisation averages 4—5 per cent. and may rise to 8 per cent., and the author has studied the question of the pressures generated during the heating. He finds that beer expands approximately 2 per cent. during heating from 0° C. to 66° C., and if this space only is left above the liquid in a hermetically closed vessel, the pressure rises to 39 atmospheres, but if only as little as 0.1 per cent. more space is left, only 21 atmospheres pressure is attained and a further 0.2 per cent. space reduces it to 11 atmospheres. With an air space of 2.5 per cent. of its volume above the beer, the pressure only reaches 8 atmospheres. The author considers that bottles intended for use in a pasteurising plant should be bought under a guarantee that they will stand a pressure of 30 atmospheres.—R. L. S.

Stout: Studies on —. N. van Laer and J. D. Wilson. *Woch. für Brau.*, 1909, 26, 6—9.

THE authors have made a number of comparative analyses of stouts and ales of approximately the same original gravities, from which it would appear that those kinds of stout which are most popular and most generally prescribed by physicians are distinguished by their high acidity, being particularly rich in non-volatile acids. Biological examination showed that the favourite stouts were heavily infected with the lactic acid bacterium, *Saccharobacillus Pastorianus*, whereas ales were comparatively free from this organism. The authors suggest that the hygroscopic nature of black malt and its caramelised condition make it a favourable medium, during storage, for the development of this species of bacterium, the spores of which are not destroyed in the process of boiling the wort. The *Saccharobacillus* was observed to occur most profusely in those stouts which were richest in assimilable nitrogen and therefore offered favourable conditions for the development of infecting organisms. Owing to the dark colour of stout, infections may be allowed to occur which would not be tolerated in the case of an ale, which is required to be quite bright, but it is known that stouts are peculiarly liable to instability. The authors suggest that the presence of lactic acid bacteria in stout is not necessarily a fault, and quote the recent investigation of Metchnikoff in support of their further suggestion that these bacteria may be actually beneficial to health, and that their presence may account for the medicinal qualities with which stout is popularly credited. The authors point out however that the lactic acid bacteria of stout differ from those of milk, studied by Metchnikoff, in the fact that they soon die in presence of the acid which they have produced.—J. F. B.

Wines with sulphide flavour: Restoration of —. G. Gimel. *Bull. Assoc. Chim. Suar. et Dist.*, 1908, 26, 478—479.

To remove sulphuretted hydrogen from wine, the author recommends the use of copper turnings (15 grms. per hl.). The metal, which may be contained in a wicker cage, is immersed in the wine for 24 hours, the wine being stirred three or four times during this period.—L. E.

Starch: [Polysaccharides from —.] Schardinger. See XVI.

PATENTS.

Whiskey-still. J. F. Jett, Carrollton, Ky., Assignor to J. F. Jett, Peoria, Ill. U.S. Pat. 908,465, Jan. 5, 1909.

THE apparatus consists of a chamber surrounded by a steam jacket and surmounted by a distilling column. A series of independent steam coils are disposed in the chamber for the purpose of generating vapour from the spent beer, the "live" beer being introduced into the upper part of the column and encountering the vapour from the spent beer at the bottom of the column. Means are also provided for exhausting the steam from the coils and for agitating the spent beer in the heating chamber. —W. P. S.

XVIII.—FOODS; SANITATION; WATER PURIFICATION, AND DISINFECTANTS.

(A).—FOODS.

Gluten in wheat flour; Determination of dry —. O. Rammstedt. Z. angew. Chem., 1909, 22, 16—18.

THE usual procedure in the determination of gluten in flour is to knead the dough with the hands under running water and to dry and weigh the residual gluten. This gluten presents considerable difficulty in drying, owing to the fact that it tends to flow together in a mass, and then to form a hard dry skin on the outside which prevents the escape of water from the inside. In order to facilitate the drying, Bremer devised perforated clay cylinders around which the slab of gluten was wrapped and thus kept distended during drying. These cylinders, however, are expensive and are not easily cleaned. Another method consists in spreading the gluten in a thin layer on the bottom of a Petri dish. The author has found, however, that the best substitute for the clay cylinders is a tinned iron spice-grater. These present the same advantages as the clay cylinders as regards rapid drying and moreover are readily cleaned after use. Determinations showed that the rate of drying on the cylinders or graters is somewhat more rapid than in Petri dishes, but the difference is not of much importance in view of the crude nature of the determination. Drying is complete in 1½ hours in an air oven at 120° C. or in a vacuum oven at 110° C., but the latter is much to be preferred, because the gluten undergoes considerable changes when heated in air.—J. F. B.

Flour; Detection of bleached. L. Weil. Chem.-Zeit., 1909, 33, 29.

WHILST the Griess-Hosvay reagent (this J., 1907, 1211) is capable of detecting very minute quantities of nitrous acid, and will show the presence of this acid in flours which have been bleached by treatment with ozonised air, the author finds that the information yielded by the test is not altogether reliable, as certain unbleached flours give a coloration with the reagent. For instance, flour from some Russian wheat gave a coloration at once; La Plata and Kansas flours reacted after standing for 5 minutes, Swedish flour after 9 minutes, and German flour after 20 minutes. These flours therefore contain normally a small quantity of nitrous acid or some other substance which gives rise to the reaction. The author

recommends the following test for ascertaining whether a flour has been bleached. A quantity of the flour is placed in a closed vessel through which a current of hydrogen sulphide is passed for one hour; the colour of the flour thus treated is then compared with that of the original sample. Unbleached flour exhibits no difference in colour after treatment with hydrogen sulphide, but bleached flour becomes darker, acquiring the original colour it possessed before bleaching.—W. P. S.

Formaldehyde in milk; Detection and determination of —. H. S. Shrewsbury and A. W. Knapp. Analyst, 1909, 34, 12—13.

TO 5 c.c. of milk in a test-tube are added 10 c.c. of a freshly prepared mixture of 0.1 c.c. of pure nitric acid and 100 c.c. of concentrated hydrochloric acid. The tube and its contents are then placed in a water-bath at a temperature of 50° C. for 10 minutes and afterwards cooled rapidly to about 15° C. A violet coloration shows the presence of formaldehyde, and its intensity indicates the amount, which may be determined by comparison in the usual way. In the case of milk free from formaldehyde, the colour remains unaltered. From 0.1 to 0.2 part of formaldehyde per million parts of milk may be detected by means of the test.—W. P. S.

Cocoanut oil; Detection of — in butter. C. Paal and C. Amberger. Z. Untersuch. Nahr. Genussm., 1909, 17, 23—51.

A METHOD is based upon the determination of the amount of insoluble cadmium salts yielded by the distilled volatile fatty acids (see following abstract) considered in conjunction with the other values of the fat. Irregularities due to variations of manipulation may be avoided by carrying out the distillation in a current of steam in a flask like that shown in the figure. This apparatus consists of a flask holding about 1½ litres, and closed by a cork through which pass the tube, B (connected with a condenser), and the tube, A. The distillation vessel consists of an upper tube, C, fitted by means of a ground-in connection into the vessel, D, into which steam is introduced from the large flask through the tube, E. The device, G, in the neck of the tube, C, prevents particles of fat or water from being mechanically carried over. In testing a fat, 2.5 grms. are saponified with 10 grms. of glycerol-soda solution (20 c.c. of 50 per cent. sodium hydroxide solution diluted to 200 c.c. with glycerin). The soap is dissolved in 50 c.c. of hot freshly-boiled water, and the solution cooled to 55° to 60° C., and treated with 25 c.c. of dilute sulphuric acid (25 c.c. H₂SO₄ per litre). After standing for 10 to 12 hours, the solidified fatty acids are collected on a porcelain filter-plate covered with filter paper, washed with 50 c.c. of cold water and introduced into the vessel, D, the filter funnel being subsequently rinsed with 5 c.c. of 1 per cent. sulphuric acid to transfer the last particles. The vessel, D, is now connected with the tube, C, and the large flask charged with 800 c.c. of water and 1 gm. of finely powdered pumice stone. Heat is applied beneath a wire gauze and so regulated that 200 c.c. of distillate are obtained in 35 to 40 minutes. The distillation is then stopped, and the condenser connected with a flask containing absolute alcohol, the distillation of 50 c.c. of which removes fatty acids adhering to the condenser tube. The combined distillates (250 c.c.) are rendered alkaline with N/10 potassium hydroxide solution, and the amount of volatile acids nearly insoluble in water determined by titration with N/10 sulphuric acid. The neutral solution

is again rendered alkaline with 1 c.c. of $N/10$ potassium hydroxide solution, and concentrated on the water-bath to 40–45 c.c. It is then transferred to a graduated cylinder, made up to 50 c.c. with water, neutralised with $N/10$ sulphuric acid, and treated with 2 c.c. of a 20 per cent. solution of cadmium sulphate (4 c.c. in the case of fats containing over 40 per cent. of coconut oil). The precipitate is collected in a Gooch crucible, washed with 50 c.c. of water, and dried at 102° – 106° C. until constant in weight. It consists of cadmium salts of caprylic, capric, and lauric acids in proportions varying with the nature of the fat; the cadmium salts of butyric and caproic acids are soluble in water. The cadmium values (in mgrms.) obtained in this way ranged from 70.0 to 90.0 in the case of 32 samples of pure butter, whilst the same samples with the addition of 10 per cent. of coconut oil gave values of 104.0 to 124.0. A sample of coconut oil gave a cadmium value of 470 and two commercial preparations of that fat, values of 455 and 441 respectively. Feeding experiments showed that only after very large quantities of coconut oil-cake had been given to the cows did the cadmium value of the butter approximate that of butter containing 10 per cent. of coconut oil. Further experiments showed that variations in the butter fat due to the period of lactation did not affect the cadmium value sufficiently to cause difficulties in judging the purity. Low cadmium values (70 to 75) were, as a rule, obtained with the butter of cows at a late stage of lactation. Owing to the variations in the cadmium values of pure butter fat, the detection of 10 to 15 per cent. of coconut oil is only possible by considering the results of this method in conjunction with other values. So far, the following limits have held good:—Butter may be regarded as adulterated with coconut oil:—(1). When the cadmium value exceeds 100 and the Jucknack-Pasternack difference lies within the limits of +4.25 and –3.5. (2). When the cadmium value exceeds 110, while the saponification value does not exceed 235 or the Jucknack-Pasternack difference exceed –8. (3). When with a saponification value not exceeding 235, but with a Jucknack-Pasternack difference of more than –8, the cadmium value exceeds 120. (4). When the cadmium value exceeds 130 and the saponification value 235. (5). Butter with a Reichert-Meissl value of 28.0 and over need not, for practical purposes, be taken into consideration.—C. A. M.

Butter fat and coconut oil; Metallic salts of the volatile fatty acids of —. C. Paal and C. Amberger. Z. Untersuch. Nahr. Genussm., 1909, 17, 1–22.

Ox precipitating the volatile fatty acids of butter fat and of coconut oil by means of salts of heavy metals, pronounced differences are obtained in the amounts of the respective precipitates, and these are especially noticeable in the case of the zinc and cadmium salts. Thus the distillate obtained in determining the Reichert-Meissl value of coconut oil yields from 3 to 6 times as much insoluble zinc salts as the distillate from pure butter fat. A mixture containing 10 per cent. of coconut oil yields almost double the quantity given by the pure butter fat, whilst a mixture containing 50 per cent. gives as much as or more than that from pure coconut oil. Thus the zinc precipitates from the volatile acids from 5 grms. of six pure samples of butter fat weighed from 41 to 125 mgrms., whilst the corresponding precipitates from two samples of coconut oil weighed 110 and 135 mgrms. respectively. Since mixtures of two kinds of pure butter with 10 per cent. of coconut oil yielded 110 and 135 mgrms. respectively of insoluble zinc salts, or as much as certain pure butters, the certain detection of small quantities of coconut oil by means of this value alone is out of the question. Similar results were obtained by precipitation with silver, cadmium, and barium salts, and it was also found that slight variations in the method of distillation of the volatile fatty acids had considerable influence upon the quantity of insoluble precipitate subsequently obtained.—C. A. M.

Flour; Bleached —. U.S. Food Inspection Decision No. 100. [T.R.]

THE Board of Food Inspection has given it as their unanimous opinion that flour bleached with nitrogen

peroxide is an adulterated product under the Food and Drugs Act, 1906; also that no statement on the label can bring such bleached flour within the law, and that such flour cannot legally be made or sold in the District of Columbia or in the Territories, or be transported or sold in interstate commerce.

Vegetables greened with copper salts; Admission of — into the United States. U.S. Food Inspection Decision No. 102. [T.R.]

VEGETABLES greened with copper salts, but which do not contain an excessive amount of copper, and which are otherwise suitable for food, will be allowed entry into the United States until further notice, if the label bears the statement that copper sulphate or other copper salts have been used to colour the vegetables.

“Denaturing” cottonseed oil. Winterfeld. See XII.

PATENTS.

Milk preparation from cows' milk; Manufacture of a —. E. Bohlen. Ger. Pat. 205,965, Jan. 29, 1908.

Cows' milk is diluted with water and mixed with a neutral solution of pure lactalbumin. One kilo. of sterilised lactalbumin is dissolved in a sterilised lye containing 60 grms. of sodium hydroxide, the excess of alkali is removed by dialysis or neutralised with acid, and a quantity of the solution containing from 3 to 6 grms. of lactalbumin is added to 1 litre of a milk food prepared in the usual manner by addition of cream, lactose, and water to cows' milk. —A. (B.)—SANITATION; WATER PURIFICATION.

Water; Colorimetric determination of dissolved oxygen in —. G. B. Frankforter, G. W. Walker, and A. D. Wilhoit. J. Amer. Chem. Soc., 1909, 31, 35–43.

THE method described depends on the change in colour of cuprous-ammonium chloride when brought in contact with oxygen (see this J., 1901, 1071) and the authors have devised an apparatus in which a solution of the pure, colourless double salt can be prepared and kept ready for use. This apparatus is shown in the accompanying figure; it is constructed entirely of glass. Copper wire is introduced into the reservoir, C, the opening in the stop-cock being large enough to admit the pieces, and C is then filled with a saturated solution of cuprous chloride in hydrochloric acid. After any cupric chloride which may be present has been reduced, the burette, A, is filled with concentrated hydrochloric acid. The tube, F, serves for mixing the cuprous chloride with the ammonia which is contained in the burette, E, the three-way tap, D, allowing the necessary quantities of the two solutions to be discharged. The reservoir, H, is filled with the sample of water, corked, placed in position, and connected with the apparatus at O; the tube, N, is connected with a hydrogen apparatus. The colorimeter tube, K, is then filled with the water by opening the tap, I, and the three-way tap, G, care being taken that all small bubbles of air are removed. The colorimeter tubes hold exactly 102 c.c. Two c.c. of the cuprous-ammonium chloride are next introduced; this is accomplished by connecting F (previously filled with reagent) with K, opening B and cautiously opening D. When 0.5 c.c. of the reagent have been introduced into K, B is closed and D is turned so as to connect E, containing ammonia, with K; 1.5 c.c. of the reagent having been admitted into K, making 2.0 c.c. in all, the tap is closed. These operations admit simultaneously quantities of cuprous chloride and ammonia to the tube, F, so that the latter is kept full of the reagent. The colorimeter tube now contains 100 c.c. of the water plus

2 c.c. of reagent, and after the tap, I, has been closed, the blue coloration produced is compared with that given by a known quantity of a standard solution of cupric chloride solution contained in a second colorimeter tube, 'K'. This standard solution is prepared by dissolving 1.1364 grms. of pure copper in *aqua regia*, evaporating the excess of acid, and diluting the residual solution to 1 litre. Each c.c. of the solution is equivalent to 1 c.c. of oxygen in a litre of water when the quantity of water taken for analysis is 100 c.c.—W. P. S.

Wood pulp mill effluents. Vogel. See XIX.

PATENTS.

Refuse consuming furnaces. W. Fairweather, London.

From Decarie Manufacturing Co., Minneapolis, U.S.A.
Eng. Pat. 28,682, Dec. 31, 1907.

THE furnace consists of a circular or rectangular combustion chamber in which is fitted a basket-grate formed of a number of water-circulating tubes; these tubes are in connection with a water and steam tank situated around and above the chamber. Wet garbage is filled into the basket-grate and is dried by the gases and flames coming from an auxiliary furnace; as it dries, the garbage falls from the basket on to a grate below, where it is consumed. The gases from the combustion chamber pass through perforated firebricks at the top of the chamber, thence downwards through a flue containing water tubes at the side of the chamber, and over the surface of water contained in a tank at the bottom of the flue. The water in this tank absorbs much of the solid or uncombusted material in the gases. The latter are then conducted under a draught furnace and into a combustion chamber in which are walls reaching almost to the top and bottom, respectively. On leaving this chamber, the gases pass through a sheet of falling water before escaping into a chimney. (See also Eng. Pat. 18,915 of 1905; this J., 1906, 492.)

XIX.—PAPER, PASTEBOARD, &c.

Wood pulp mills; Effluents from —. J. H. Vogel.
Z. angew. Chem., 1909, 22, 49—55.

THE pollution of rivers by the effluents from sulphite wood pulp mills may be direct, *e.g.*, by fibres, dissolved organic matters, and sulphurous acid, or indirect, *e.g.*, by the growth and subsequent putrefaction of fungi and algae. Of the first class of polluting substances, the cellulose fibres are the most objectionable and the most easily removed. These fibres collect and precipitate impurities from sewage effluents and effluents of other factories, and are deposited in the form of a putrefying mud at the bottom of the river. In cases of damage due to pollution, *e.g.*, fish poisoning or damage to crops after floods, the ease with which the fibres are identified causes the responsibility to be thrown on the pulp mill, even though the fibres are harmless in themselves and constitute only a small proportion of the mud. The cost of removing the fibres from the effluent is largely counterbalanced by the value of the recovered product, so that all mills should aim at discharging an effluent containing not more than 40—60 mgrms. of suspended fibres per litre, according to the size of the river. The waste liquors themselves, if diluted 100 times, are perfectly harmless to fish and to vegetation, thus no direct damage is likely to ensue from their presence in the river. But the indirect nuisance caused by the growth and putrefaction of fungi may assume very grave proportions in a slow-flowing river. The waste liquors at their original concentration are absolutely non-putrescible; the growths are developed by the continuous feeding of the lyes into the channel in a highly dilute form. A mill producing 40 tons of cellulose per day will discharge about 300 cub. m. of original lye and 780 cub. m. of wash-waters. The lye will very rarely contain 4 grms. of free sulphur dioxide per litre, and this will be largely neutralised by the basic constituents of the wash-waters. The best method of preventing growths is to adopt the system of periodical discharges of large quantities of lye instead of the continuous discharge of small quantities. The lyes and washings should be collected in a reservoir, freed from fibres, and discharged once or twice every 24 hours at such a rate that the total dilution of the original lye amounts to 100 times. The time of discharge might be about 40 minutes, but every case requires particular consideration; much depends also on the degree of pollution by putrescible and de-oxidising effluents from other sources. The author is opposed to the regulation requiring the neutralisation of the effluents by lime. A neutral or alkaline condition of the lyes greatly favours the growth of fungi. It would seem that the apparently "free" sulphurous acid in these lyes is probably in loose combination with the sugars, and is far less poisonous to fish than pure sulphurous acid. All that is necessary is to ensure that the "free" sulphurous acid does not amount to more than 1 gm. per litre of effluent; the basic matters in the river water will then do all that is necessary. In the case of very small water-courses, if the periodical discharge of the effluent be adopted, it may be necessary to dilute the lyes in the reservoir before discharging.—J. P. B.

Swedish paper pulp in the United States; Extra duty on —. Papier-Zeit., 1909, 34, 2. [T.R.]

ACCORDING to the United States tariff, the customs officials can assess on an increased scale any goods on which, or on the materials used in the manufacture of which, the exporting country levies an export duty. It has only just come to the knowledge of the officials that, according to a decree of the Swedish Government, which came into operation in 1905, wood, mechanical wood pulp and cellulose, exported from certain districts of Sweden, are subject to an export duty. This tax is levied in order to cover the expenses of the Government supervision of the forests, and it amounts to 0.66 to 1.32d. per cub. metre of wood, 6.59d. per ton of dry cellulose pulp, and 3.96d. per ton of dry mechanical pulp. The export duty on moist pulp is one-half that on dry pulp.

The U.S. Customs have now decided to charge an extra duty of 13½ cents per ton (2,240 lb.) on Swedish pulps, over and above the tariff duty.—J. F. B.

Paper; Relations between moisture-content and strength of —. L. Friedrich. *Papierfabrikant*, 1909, 7, 7—8.

It is well known that the mechanical properties of paper are influenced by the percentage of hygroscopic moisture present in the paper at the time of testing. With increased percentage of moisture, there is a decrease in tensile strength and, up to a limit, an increase in the extensibility and in the resistance to creasing and rubbing. In recognition of this variation it is customary, when great accuracy is desired, to allow the paper to remain for a few hours in an atmosphere artificially maintained at a humidity of 65 per cent., before testing. The author's investigations have shown that when paper had been stored in an atmosphere of 40 per cent. humidity (a condition by no means rare in dry rooms), and was then transferred to the standard atmosphere for testing, 2 hours in this latter atmosphere were not sufficient for the establishment of a new equilibrium. The time required for the complete conditioning of the paper varied with its nature, being least in the case of ordinary "news" paper. With papers of better quality it was necessary to leave the papers in the standard atmosphere for at least six hours before results comparable with those obtained after 24 hours' exposure were obtained. For instance, with a normal paper of the class 2a, transferred from an atmosphere of 40 per cent. humidity to one of 65 per cent., the hygroscopic moisture rose from 6.3 per cent. after 2 hours' exposure to 6.7 per cent. after 6 hours. Coincident with this change in the moisture-content of the paper, the "breaking length" fell from 5215 to 5030 m., the "elongation" rose from 3.80 per cent. to 4.05 per cent., and the resistance number on Schopper's creasing machine rose from 213 to 224. These variations are far from being negligible, and the time required to establish equilibrium would of course be very much greater if the paper were originally in a drier condition than that corresponding with an atmosphere of 40 per cent. humidity.—J. F. B.

Cellulose solutions; Process for the production of —. E. Crumière, Paris. U.S. Pat. 908,754, Jan. 5, 1909.

SEE Fr. Pat. 361,048 of 1905; this J., 1906, 691.—T. F. B.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENTIAL OILS, AND EXTRACTS.

Alkaloids in coca leaves; Determination of —. A. W. K. de Jong. *Rec. trav. chim. Pays-Bas*, 1908, 27, 419—421.

THE author prefers the following method for estimating the alkaloids in coca leaves instead of the Keller-De Jong process. 12.5 grms. of finely powdered leaves are mixed with 5 c.c. of 25 per cent. ammonia and the mixture extracted in a Soxhlet apparatus with light petroleum for 10 to 15 hours. After transferring the extract to a stoppered funnel and washing out the flask with light petroleum, the leaves are extracted again for 3 hours and the light petroleum tested by shaking it with 2 or 3 c.c. of dilute hydrochloric acid; the acid should not give a turbidity with ammonia. The alkaloid extract is now shaken with 50 c.c. and then with 25 c.c. of dilute (0.5 per cent.) hydrochloric acid. When an emulsion is formed, this is transferred to a flask and the liquids separated by a current of air. The acid solution is then filtered through a small filter previously washed twice with water. The filtrate is shaken once with ether (which is set aside) and rendered alkaline with ammonia. It is then shaken first with 50 and then with 25 c.c. of ether, the ethereal solution allowed to stand for a few minutes, transferred to a tared flask (care being taken not to pour in any drops of water), the flask washed twice with a few c.c. of ether, which are added to the bulk, the solution evaporated, and the flask heated several times

in boiling water; after each heating a current of air is passed through. The flask is finally dried in a desiccator and weighed.—J. C. C.

Quinine sulphate; [Official description of —]. L. Vaudin. *J. Pharm. Chim.*, 1909, 29, 60—61.

ACCORDING to the French Codex of 1884, quinine sulphate was tested by means of ammonia, a method which allowed the presence of as much as 5 per cent. of the salts of quinidine and cinchonidine. The Pharmacopœa of 1908 has introduced tests which are only satisfied by pure quinine sulphate. Pure quinine sulphate satisfying these conditions will cost about 45 per cent. more than that produced in accordance with the former requirements. The author suggests that less stringent tests should be introduced to prevent inconvenience owing to the increased cost of pure quinine sulphate. The new Pharmacopœa comes into force on May 15th next.—F. SHON.

Amara milk; Preliminary note on the composition of —. A. Rathje. *Arch. Pharm.*, 1909, 247, 49—53.

AMARA milk is used in the Amazon region as a remedy for consumption. It is the latex of one of the *Apocynaceæ* indigenous to Brazil, possibly a species of the genus *Hancornia*. The following substances were found to be present in the milk: plant acids, gelatinous substances; sugars; esters of tannic acids; water; esters of formic, acetic, propionic, and butyric acids; fatty acids melting at 53°—54° C., 63°—64° C., 69°—70° C., 78°—79° C.; phytosterol; and hydrocarbons of the melting points, 120°—121° C., 196°—197° C., 200°—201° C., and 201°—205° C. The milk has the sp. gr. 1.0304, a sour taste, and an acid reaction.—F. SHON.

Tolu balsam; Detection of rosin in —. E. Perrot and A. Goris. *Bull. Sci. pharm.*, 1908, 636. *Apoth.-Zeit.*, 1909, 24, 9.

FIVE grms. of Tolu balsam are shaken with 30 c.c. of carbon bisulphide in the cold, or with gentle warming. The solvent is decanted and evaporated; the residue is treated with 10 c.c. of light petroleum spirit, filtered, and shaken with a 1 per 1000 solution of copper acetate. The presence of rosin is indicated by the appearance of a green colour. Two per cent. of rosin, or less, may be detected thus. The test is not applicable to Peruvian balsam, for the pure drug gives a green colour under these conditions.—J. O. B.

Lemon oil; Determination of aldehydes in —. A. H. Bennett. *Analyst*, 1909, 34, 14—17.

THE method described is a slight modification of that proposed by Walther (this J., 1899, 1161); in order to overcome the objection that the carbon dioxide evolved carries off hydroxylamine, the author, instead of using sodium bicarbonate, adds to the solution of the hydrochloride a quantity of an alcoholic solution of potassium hydroxide sufficient to liberate an amount of hydroxylamine in excess of that required to combine with the citral present, but not sufficient to completely neutralise the acid of the hydrochloride. Such a partially-neutralised solution can be boiled under a reflux condenser without any loss of the base taking place. The details of the process are:—Twenty c.c. of lemon oil are mixed with 20 c.c. of $N/2$ solution of hydroxylamine (in 80 per cent. alcohol) and to the mixture are added about 8 c.c. of $N/4$ alcoholic solution of potassium hydroxide and 20 c.c. of alcohol. The mixture is boiled under a reflux condenser for 30 minutes, then allowed to cool, the condenser is washed, and the contents of the flask are diluted with 250 c.c. of water. The solution is next made neutral to phenolphthalein, and finally titrated with $N/2$ sulphuric acid, using methyl orange as indicator. The number of c.c. of acid required, subtracted from the number used in a blank experiment in which no lemon oil is present, represents the amount of hydroxylamine which has combined with the citral, and multiplied by 0.076 gives the weight of citral. It is recommended that drops of an aqueous solution of methyl orange placed on a white plate be used in the titration.—W. P. S.

Lemon oil; [*Adulterated* —]. E. J. Parry. Chem. and Drugg., 1909, 74, 121.

THE author states that since the earthquake in Sicily, a great deal of grossly adulterated lemon oil has appeared on the market. He gives particulars of various samples adulterated with petroleum, castor oil, and oil of turpentine, and of others diluted with lemon oil terpenes; these latter were possibly so-called "super-oil."—A. S.

Eucalyptus globulus oil; *South African* —. E. F. Harrison. Pharm. J., 1909, 82, 4.

A SPECIMEN of *Eucalyptus globulus* oil from the Transvaal had the following characters:—Sp. gr. 0.9227 at 15° C.; $[\alpha]_D^{20} = +3.33'$; cineol content, 83.7 per cent. by the phosphoric acid method; no phellandrene was present. The oil is of good quality for medicinal use.

—J. O. B.

Atoxyl [*sodium p-aminophenylarsinate*]; *Distinguishing* — from *arsacetin* [*sodium p-acetaminophenylarsinate*]. A. Labat. Bull. Soc. Pharm. Bord., 1908, 289. Pharm. J., 1909, 82, 60.

THE chief advantages of arsacetin over atoxyl are that it may be sterilised in an autoclave at 130° C. without decomposition, and that it is less toxic. It may be distinguished from atoxyl by a number of reactions, among which are the following:—Ten per cent. aqueous solutions are used. On mixing a drop of the atoxyl solution on an object glass with a drop of a 1 per cent. solution of cobalt nitrate, nickel chloride, manganese sulphate, or magnesium sulphate, there is obtained a crop of small crystals, sometimes resembling those of ammonio-magnesium phosphate. In the case of manganese sulphate, a small part of the precipitate is amorphous, but all the rest is crystalline. Arsacetin, on the contrary, gives an amorphous precipitate with cobalt nitrate and manganese sulphate, but none at all with the other reagents. On mixing 1 c.c. of 95 per cent. alcohol and two drops of atoxyl solution, a crystalline precipitate is formed, but none with arsacetin. On mixing 1 c.c. of the atoxyl solution with 1 c.c. of 5 per cent. sulphuric acid, there is formed a very slight crystalline deposit; with a solution of half the strength there is no reaction. Arsacetin, under these conditions, gives a precipitate so dense that a magma is produced. In both cases the crystals are in the form of hexagonal tables. On adding bromine water, drop by drop, to 1 c.c. of the atoxyl solution, there is formed an amorphous precipitate surmounting a pale yellow liquid. With arsacetin the precipitate formed is deposited in tufts of fine needles, easily observed under slight magnification. When 0.20 grm. of arsacetin is heated with 10 c.c. of a mixture of equal parts of alcohol and sulphuric acid, the odour of ethyl acetate is given off; atoxyl gives no such odour.

Salicylic acid; *Reduction of* —, to *salicylic aldehyde*. H. Weil. Ber., 1908, 41, 4147—4148.

IN presence of excess of boric acid, sodium amalgam is capable of reducing sodium salicylate to salicylic aldehyde; 15 grms. of salicylic acid neutralised by 5.5 grms. of sodium hydroxide are diluted to 1 litre with hot water, 18 grms. of *p*-toluidine dissolved in it, and the whole is cooled with constant stirring. Then 15 grms. of boric acid are added, and, gradually, 330—430 grms. of 2 per cent. sodium amalgam. During this addition, the liquid must be constantly stirred, and boric acid added so as to keep the solution always slightly acid (about 120 grms. in all). The suspended aldehyde-toluidine is filtered off, acidified, and distilled in steam, when the aldehyde passes over and toluidine salt remains.—J. T. D.

Benzoic and salicylic acids; *Electrolytic reduction of* —, to *aldehydes*. C. Mettler. Ber., 1908, 41, 4148—4150.

THE reduction by sodium amalgam discovered by Weil (see preceding abstract) can be modified so as to make use of the electrolysis of a sodium salt. A solution of sodium sulphate is in the first instance electrolysed with a mercury cathode so that the electrolysis of the sodium salicylate may be started with a sodium amalgam electrode; the solution of sodium salicylate and boric acid is then

placed in the cell, with a quantity of benzene, and electrolysis begun with constant mechanical agitation. As the aldehyde is formed, it dissolves in the benzene; and at the end of the operation the benzene and aldehyde are distilled over in steam, and afterwards separated. Many substituted benzoic acids can be reduced in this manner.

—J. T. D.

Methylaniline and dimethylaniline; *Recognition of* — in the presence of each other. H. Emde. Arch. Pharm., 1909, 247, 77—79.

THE platinum salts can be used to distinguish between methylaniline and dimethylaniline in the presence of each other. Methylaniline platinum chloride, $(\text{BHCl})_2\text{PtCl}_4$, forms short orange-coloured crystals, which decompose at 199° C., and can be crystallised from hot water containing hydrochloric acid. Dimethylaniline platinum chloride, $(\text{BHCl})_2\text{PtCl}_4$, is produced by dissolving the base in strong hydrochloric acid, and adding the solution to 10 per cent. platinum chloride solution. The orange-yellow precipitate is filtered off in the cold and recrystallised from alcohol containing hydrogen chloride. It then forms orange-red needles, decomposing at 173° C. If a mixture of the bases is suspected, a small portion dissolved in acid is added to a platinum chloride solution, and the platinum double salts separated by crystallising from alcohol. If methylaniline only is to be looked for, the mixture can be crystallised from water. The presence of 5 per cent. of methylaniline in dimethylaniline can be recognised in this way.—F. SUPN.

Iodoform; *Action of* — on *silver fluoride and chloride*. O. de Coninck. Bull. Soc. Chim., 1909, 5, 62—63.

BY the action of silver chloride, in the presence of water at 94° C., iodoform is converted into chloroform, and silver iodide is formed. With silver fluoride, however, the reaction may be represented by the equation,

the evolved gas generally containing also a little carbon dioxide.—F. SUPN.

Benzoic acid into salicylic acid. Bargellini and Inghilleri. See XIA.

PATENTS.

Dihalogen-acetyl chloride, dihalogen-acetic acid, and derivatives thereof; *Manufacture of* —. H. K. Tompkins, and The Clayton Aniline Co., Ltd., Manchester. Eng. Pat. 5104, March 10, 1908.

THE tetra-halogen compounds obtained by treating dichlorovinyl ether, $\text{CHCl}:\text{CClOC}_2\text{H}_5$, with chlorine or bromine, are decomposed into ethyl chloride or bromide and dihalogen-acetyl chlorides, by heating. The latter react slowly with water forming the corresponding dihalogen-acetic acids; with ammonia, dihalogenated acetamides are formed, and with aniline the anilides of the acids; with alcohol they yield ethyl dihalogen acetic esters.—T. F. B.

Formic acid; *Manufacture of* —. Soc. Anon. des Établissements Eycken et Leroy. Fr. Pat. 393,526, May 21, 1908.

SODIUM formate, alone, or in the presence of formic or acetic acid, is distilled with oxalic acid, the resulting sodium oxalate is converted into caustic soda and calcium oxalate by means of lime, and oxalic acid is recovered from its calcium salt by means of sulphuric acid, the object being to recover the oxalic acid used, and also the soda (as sodium hydroxide) whilst formic acid is distilled off and condensed in the usual way.—O. R.

Purine derivatives; *Process for producing new* —. Farbenfabr. vorm. F. Bayer und Co. Fr. Pat. 393,564, Aug. 12, 1908. Under Int. Conv., Feb. 22 and 26, 1908.

BY treating 4,5-diaminopyrimidines with halogen derivatives of organic acids, water is eliminated between the acid and the 5-hydroxy group; the halogen-acylaminoaminopyrimidines thus formed react with ammonia,

the halogen group being replaced by an amino-group; by treating these compounds with condensing agents (e.g., alkali hydroxides), water is eliminated and purine derivatives are obtained. Thus, from monochloroacetic acid and 1,3-dimethyl-2,6-dioxy-4,5-diaminopyrimidine, the amino compound and its conversion into the purine derivative are as follows:—

—T. F. B.

Mercury salt solutions; Preparation of stable —. A. Busch. Ger. Pat. 204,932, Nov. 23, 1907. Addition to Ger. Pat. 187,697.

COMPOUNDS of mercuric salts with hexamethylenetetramine are obtained in stable solution by dissolving the double salt in excess of soap solution, with addition of sufficient albumose to prevent precipitation of the mercury by the usual reagents. A solution corresponding to a 1 per cent. mercuric chloride solution is obtained by mixing 1.26 grms. of hexamethylenetetramine-dimercuric chloride with an equal weight of albumose, and stirring the mixture into 97.5 c.c. of a 5 per cent. soap solution until solution is complete.—T. F. B.

Gallie acid salts; Preparation of dry, stable —. Knoll and Co. Ger. Pat. 204,959, Feb. 6, 1908.

SOLUTIONS of gallates extracted from fresh galls, and purified in the known manner and extracted with chloroform, are mixed with gum tragacanth; they can then be evaporated to dryness at temperatures below 55° C. The resulting preparations are nearly colourless, and insoluble in ether and chloroform; alcohol extracts the gallate, leaving the tragacanth undissolved.—T. F. B.

Camphene free from chlorine; Process for preparing solid —. A. Roesler. Ger. Pat. 205,295, Jan. 26, 1908.

THE halogen acid is said to be quantitatively removed from pinene hydrohalides by heating for 24 hours under pressure with a meta- or pyroborate, silicate, phosphate, or arsenate, in aqueous solution; the camphene is isolated by distillation with steam. 10 kilos. of solid pinene hydrochloride, 13.8 kilos. of crystallised borax, and 15 litres of water are heated for 24 hours in an autoclave, at 220° C. The camphene obtained (yield 97 per cent. of theory) is free from chlorine and boils below 160° C.—T. F. B.

Sodium-amino compounds, alone or mixed with potassium-amino compounds; Process for preparing — from primary or secondary aromatic amines. Basler Chem. Fabrik. Ger. Pat. 205,493, April 7, 1906.

COMPOUNDS of sodium with aromatic amines are readily obtained by the action of the metal on the amine in presence of sodium or potassium hydroxide; if potassium hydroxide is used, a mixture of the sodium and potassium compounds is formed. For example, 50 grms. of dry potassium hydroxide are heated in an iron vessel to 200° C., 11.5 grms. of sodium are slowly added, and 47.5 grms. of aniline are then gradually added, under a reflux condenser. The product is a reddish-brown, crystalline mass.

—T. F. B.

Sodium glycerylphosphate; Process for the preparation of —. J. A. Wülling. Ger. Pat. 205,579, April 30, 1908.

SODIUM metaphosphate or a mixture of disodium phosphate and metaphosphoric acid is heated with excess of glycerin *in vacuo* to 120°–210° C., and the resulting monosodium glycerylphosphate is converted into the disodium compound in the usual manner.—A. S.

Hydrazoic acid; Process for the preparation of —. R. Stollé. Ger. Pat. 205,683, March 10, 1908.

By treating hydrazine hydrate or salts of hydrazine with nitrous acid esters, or with nitrous acid and alcohols, in alkaline solution, good yields of hydrazoic acid are obtained. *Example*.—1 kilo. of hydrazine hydrate is boiled for 24 hours with 4 kilos. of amyl nitrite and a solution of 3 kilos. of potassium hydroxide in 15 kilos. of alcohol. The alcohol is then distilled off, amyl alcohol removed by distillation with steam, and the residue diluted with water to 10 litres and boiled for 3 hours after addition of 2.5 kilos. of ammonium sulphate. After cooling, 1 kilo. of sulphuric acid is added, and the hydrazoic acid recovered from the solution by distillation. A yield of 70–80 per cent. of the theoretical quantity of hydrazoic acid is obtained.

—A. S.

Cascara sagrada bark; Process for the preparation of a clear extract, soluble in water, not containing zinc, and free from bitterness, from —. M. Penschuck. Ger. Pat. 206,467, Oct. 10, 1907.

THE powdered bark or its concentrated aqueous extract is heated with zinc oxide and water, filtered, and the filtrate evaporated in a vacuum. If any zinc sulphate is formed in the treatment with zinc oxide, this is removed by means of a small quantity of alkali carbonate.—A. S.

Camphor; Process for the manufacture of —. Dr. Schmitz and Co., Dusseldorf, Germany. Eng. Pat. 3750, Feb. 19, 1908. Under Int. Conv., March 12, 1907.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

PATENTS.

Screens with polychrome divisions for the photography of colours; Process for obtaining —. J. M. Borrel. Fr. Pat. 393,557, Oct. 29, 1907.

A GELATIN film is sensitised by means of a bichromate or other substance which is converted, by the action of light, into a mordant for the dyestuffs to be used for colouring the screen, whilst, at the same time, the unaltered sensitiser acts as a resist for the dyestuff. One-third of the sensitised film is exposed to light, washed, and dyed with the first colour; it is then again sensitised and the process repeated with the second and third colours, the resulting screen being thus composed of a series of small areas in the three colours.—T. F. B.

Paper or similar substance; Process of glazing — for use as a temporary support for photographic and cinematograph films during the manufacture of the latter. L. L. T. Labbé and H. E. Perret. Fr. Pat. 393,627. Aug. 24, 1908.

STRIPS of paper or linen are treated with a solution containing 5 grms. of celluloid in 100 grms. of acetone; the strips are then dried and coated with a varnish consisting of a mixture of 50 c.c. of petroleum spirit and 50 grms. of a paste prepared by grinding together white copal and boiled linseed oil. When the varnish has dried, a coating of gelatin is applied; this is prepared by dissolving 10 grms. of gelatin in 100 c.c. of hot water, adding 4 c.c. of glycerin, and then, immediately before use, 0.5 gm. of either formaldehyde, potassium bichromate, or aluminium acetate. Finally, a coating of a solution of 10 grms. of wax in 100 c.c. of alcohol is applied.—W. P. S.

Gelatin film for use in cinematography, and process of making the same. L. L. T. Labbé and H. E. Perret. Fr. Pat. 393,628, Aug. 24, 1908.

A GLAZED strip of paper or linen prepared as described in the preceding abstract is coated with the gelatin solution also there described. After being dried for about 24 hours at a temperature of 30° C., the film is varnished with the copal solution, and again dried for 24 hours. The varnished gelatin film is then detached from the prepared paper strip and the surface of the film which was in contact with the paper strip is varnished and allowed to dry. The gelatin solution and the varnish may be decolorised by the addition of a small quantity of oxalic acid.—W. P. S.

Photographic developing and fixing solutions. F. Jeannot and M. Bremner, Paris. Eng. Pat. 15,657, July 23, 1908. Under Int. Conv., July 23, 1907.

SEE Fr. Pat. 390,265 of 1907; this J., 1908, 1041.—T. F. B.

XXII.—EXPLOSIVES, MATCHES, &c.

Smokeless powders; Indicators and stabilisers in —. A. Carneiro. Z. ges. Schiess- und Sprengstoffwesen, 1909, 4, 29—30.

THE author has made some experiments on the addition of diphenylamine to smokeless powders, as regards its effect upon the heat test. Guttman's diphenylamine test papers were used. One grm. of the nitrocellulose powder was taken for the tests, which were carried out at a temperature of 80° C. In the case of nitroglycerine explosives the temperature was 70° C. The nitrocellulose powders having an original heat test of 9 to 11 minutes showed a drop in heat test of $\frac{1}{2}$ to 3 minutes after the addition of 1 per cent. of diphenylamine. The nitroglycerine explosives of 18 and 29 minutes heat test showed a drop of 1 to 4 minutes under similar conditions. After heating for 72 hours at 38° C., similar nitrocellulose powders showed a rise in heat test of 3 to 5 minutes, whilst the same samples containing diphenylamine showed a rise of only about $\frac{1}{2}$ to 1 minute. A similar treatment of nitroglycerine explosives gave a drop in heat test of 4 to 10 $\frac{1}{2}$ minutes in the untreated explosive and 9 to 12 $\frac{1}{2}$ minutes in the same samples containing diphenylamine. The author concludes that diphenylamine cannot be considered as a stabiliser for smokeless powder.—G. W. M. D.

Explosives; Gases resulting from the use of high —. W. Collen. J. Chem. Met. and Min. Soc., S. Africa, 1908, 9, 144—152.

THEORETICALLY, the gases evolved by the explosion of a scientifically constituted blasting gelatin are carbon dioxide, nitrogen, and water vapour, all of which are comparatively innocuous, and the results of tests made on modern blasting gelatin, in steel bombs, are found to approximate closely to the theoretical. In order to test if carbon monoxide was also formed, as has been stated, the author has collected and analysed a large number of samples of mine air, immediately before and after blasting. The samples were taken at a depth of 1400 to 1700 ft. Comparative tests were made, using newly-made blasting gelatin, three months old gelatin, a patent "neutralizer" or "anti-fume" mixture, and a gelatin of "special" composition. In every case, carbon monoxide was found in dangerous quantity (0.467—1.28 per cent.), a slight improvement however being shown when using the "special" gelatin, but even in this case, the ratio of carbon monoxide to dioxide was 1 to 9. A considerable quantity of carbon monoxide was also generated by the burning of the fuse, 96 ft. of which was generally required for each "blast." Electric firing is therefore preferable. Experiments in tamping, showed that a slight improvement was caused by the use of "Daga," a preparation somewhat resembling clay, in place of the usual sand cartridges. Details of the experiments and analyses are included in the paper, which is the first of a series of three or four.—F. B.

Regulations for the manufacture of explosives with use of dinitrobenzol or dinitroethanol. Statutory Rules and Orders No. 1310, [T.R.] See under IV.

PATENTS.

Explosives. F. W. Bawden, Johannesburg, Transvaal. Eng. Pat. 20,279, Sept. 26, 1908. (See also Eng. Pat. 4046 of 1908; this J., 1908, 923.)

LAMPBLACK and molasses are added to potassium chlorate for the purpose of imparting plasticity and to render the explosive waterproof. Nitrates of barium, potassium, or ammonium may be substituted for the whole, or a part of the potassium chlorate. Three specific mixtures for various purposes are claimed.—C. J. G.

Nitrocellulose powders; Process for the preparation of gelatinous —. Cyanid Ges., Ges. m. b. H. Ger. Pat. 265,762, Dec. 23, 1905. Addition to Ger. Pat. 201,215.

INSTEAD of adding cyanamide, dicyanodiamide, or tri-cyanotriamide to powders composed of nitrocellulose or of nitrocellulose and nitroglycerin, as described in the main patent (see Eng. Pat. 27,515 of 1903; this J., 1905, 44) salts of dicyanodiamidine are added.—A. S.

Matches. L. Carré, London. Eng. Pat. 117, Jan. 2, 1908.

PIECES of straw, haulms, rushes, or grass are dipped in a celluloid solution, or other inflammable substance, such as a liquid animal, vegetable, or mineral fat, or a mixture of these. They are then heated in an oven to remove superfluous fat, and afterwards dipped in the match composition.—A. S.

Blasting powder. H. D. Fairis and A. C. Jex, Wetaskiwin, Canada. Eng. Pat. 20,574, Sept. 30, 1908.

XXIII.—ANALYTICAL CHEMISTRY.

APPARATUS.

PATENT.

Thermo-elements; Improving the junctions of —. A. Rittershausen. Ger. Pat. 205,009, May 1, 1907.

IRREGULARITIES, such as grooves or ridges, are formed in the faces of the metals to be joined, and union is then effected by means of electrolysis, pressure, or the like, but not by soldering.—A. S.

INORGANIC—QUANTITATIVE.

Nitric acid; Determination of — gravimetrically. A. Hes. Z. anal. Chem., 1909, 48, 81—98.

AN examination of Busch's gravimetric method of determining nitrates (this J., 1905, 291, 638) shows that the solution should contain about 0.1 per cent. of nitrate, and, after the addition of "nitron," the solution (e.g., a sample of water) should be diluted or concentrated to that strength. Dextrin, gelatin, and probably other organic compounds hinder the crystallisation of the "nitron" nitrate, but the presence of aluminium sulphate, magnesium sulphate, ammonium sulphate, potassium phosphate, magnesium chloride, tartaric acid, citric acid, sucrose, and dextrose does not affect the accuracy of the method, provided the precipitate is sufficiently washed; oxalic acid causes high results. Chloric acid precipitates "nitron" quantitatively as the chlorate, if the solution contain about 0.25 per cent. of chloric acid, and nitric and chloric acids may be determined in the presence of each other, if the quantity of one be known.—F. SONX.

Sulphite; Determination of — by titration with permanganate. J. Milbaner. Z. anal. Chem., 1909, 48, 17—24.

THE determination of sulphites by titration with permanganate is unsatisfactory unless special precautions are taken, because oxidation to sulphuric acid is not quite complete. Good results are obtained if the very dilute sulphite solution, containing not more than 1 mgrm. of sulphur dioxide per c.c., be added to ten times the calculated quantity of permanganate solution (1 c.c. = 1 mgrm. of sulphur dioxide), acidified with more than 20 volume per cent. of strong sulphuric acid, and the excess of permanganate be titrated with standard oxalic acid, ferrous sulphate, or hydrogen peroxide solution. Some substances, such as bromine and iodine, when added in traces, exert a favourable influence on the reaction.

—F. SONN.

Halogen; Determination of — gravimetrically by means of silver nitrate. E. Alefeld. Z. anal. Chem., 1909, 48, 79—80.

THE time required for a determination of halogen by the usual gravimetric method with silver nitrate may be considerably shortened by the addition of ether before precipitation. The solution containing the halogen is added to about 5 c.c. of ether, and then 5 c.c. of dilute nitric acid are introduced, and silver nitrate solution added, drop by drop, with careful swirling of the liquid, until the finely divided precipitate begins to clot together and settle. The liquid is then filtered, before it becomes clear, through a Gooch crucible, previously heated until of constant weight and moistened with ether, whereby a clear filtrate is obtained immediately, and, after washing with cold water, the precipitate is dried and heated to incipient fusion.—F. SONN.

Potassium in animal liquids; Volumetric determination of —. W. A. Drushel. Z. anorg. Chem., 1909, 61, 137—146.

THE liquid is evaporated to dryness and if no albumin is present, the residue is oxidised with a mixture of nitric and sulphuric acids (9:1); in presence of albumin, oxidation is effected with bromine or with nitric acid alone, in the latter case the oxidised residue being moistened with concentrated sulphuric acid and again heated. The product is then dissolved in dilute acetic acid, and the potassium determined as described previously (this J., 1907, 1256). If the potassium cobaltinitrite precipitate be washed with sodium chloride solution instead of with water, the asbestos filter need not be so tightly packed.

—A. S.

Barium; Volumetric determination of —. A. E. Hill and W. A. H. Zink. J. Amer. Chem. Soc., 1909, 31, 43—49.

THE method is based on the precipitation of barium as iodate and on the oxidising action of this compound upon a solution of an iodide, with subsequent titration of the free iodine. A quantity of the solution of the soluble barium compound (hydroxide, chloride, bromide, iodide, nitrate, acetate, etc.) equivalent to about 0.1 grm. of barium is rendered faintly alkaline by the addition of ammonia, which should be free from carbonate; water is added to make the volume up to about 70 c.c., and a solution of potassium iodate (containing about 36 grms. of the salt per litre) is run in, the mixture being well stirred meanwhile. A sufficient quantity of the iodate to precipitate the barium together with an excess of about 25 c.c. is added in all. After 5 minutes stirring, the precipitate is collected on a filter, washed three times with concentrated ammonia, and then three or four times with 95 per cent. alcohol. The precipitate and filter are transferred to a flask, water is added, and then 50 c.c. of a 10 per cent. solution of potassium iodide free from iodate. After the addition of 10 c.c. of concentrated hydrochloric acid, the liberated iodine is titrated with a standardised solution of sodium thiosulphate. Every twelve mols. of thiosulphate used are equivalent to one atom of barium. The presence of small amounts of sodium, potassium,

ammonium, or magnesium compounds is without effect on the accuracy of the results obtained by the method, but large proportions tend to the formation of occluded iodates which count as barium in the final titration. Calcium and strontium, except in traces, must not be present.—W. P. S.

Copper; Permanganate method for determining —. F. G. Hawley. Eng. and Min. J., 1908, 86, 1155—1156.

THIS method has been in use for three years, at the Cananea Consolidated Copper Company's works, where it is daily checked by the electrolytic method and found to agree within about 0.04 per cent. with careful work. The assay occupies about 30 minutes and 20 determinations can be completed in an hour and a half. 0.5 grm., or more, of the ore is treated with 10—12 c.c. of a mixture of sulphuric and nitric acids (1:3) and rapidly boiled until dense fumes of sulphuric anhydride are evolved. After cooling slightly, the mixture is diluted with 35 c.c. of water and just neutralised with ammonia. 4 c.c. of hydrochloric acid are then added and the copper and iron reduced by the addition of 10 c.c. of a 20 per cent. solution of sodium sulphite. The solution is then boiled and the copper precipitated by 5 c.c. of a 4 per cent. solution of potassium thiocyanate. The boiling is continued for a few minutes, but before all the sulphurous acid has been expelled, the assay is set aside, and after 5 minutes, the solution is filtered, and the precipitate washed with a small quantity of hot, but not boiling, water. The precipitate is decomposed, on the paper, by a boiling 6 per cent. solution of sodium hydroxide, into soluble sodium thiocyanate and insoluble cuprous hydroxide. After well washing the residue, the filtrate is acidulated with sulphuric acid and the liberated thiocyanic acid titrated with a standard solution of potassium permanganate, 1 c.c. of which is equivalent to 0.01 grm. of iron. The iron value multiplied by 0.197 gives the copper content. Copper thiocyanate is not absolutely insoluble, but under similar conditions the loss is practically constant. It has been found that 0.005 grm. of copper remain in solution, but a partial compensation is made by the presence of small amounts of oxidisable matter, so that an allowance of 0.0025 grm. of copper should be added to the amount of copper found. Where extreme accuracy is not required, the permanganate solution may be made so that each c.c. is equivalent to 1 per cent. of copper on 0.5 grm. of ore. If the ore contains tale, clay, or similar minerals rendering filtering slow, 4 to 8 drops of hydrofluoric acid should be added to the acids used for decomposing the ore. No metal commonly found in ores is said to interfere with the accuracy of the results.—F. R.

Antimony and tin; Gravimetric determination of —. E. Cahen and G. T. Morgan. Analyst, 1909, 34, 3—9.

THE authors have submitted to a critical examination various methods which have been proposed for the determination of antimony and tin. The method described by Vortmann and Metzl (this J., 1905, 942) is capable, under certain narrowly defined conditions, of affording a quantitative separation of antimony from tin. Whilst the antimony thus separated may be weighed as the trisulphide after the latter has been heated to 150° C. in an atmosphere of carbon dioxide, no simple method is available for the determination of the tin in the filtrate from the antimony trisulphide. Phosphoric acid appears to be precipitated along with the stannic sulphide, when the tin is thrown down as sulphide. In order that the method may be effective, it is essential to avoid the presence of nitric acid or other oxidising agent, a condition not readily attained when antimony and tin are to be separated from the other metals of the sulphide group. Czerwek's method (this J., 1906, 829) was found to be trustworthy for the separation and determination of tin, but quite useless for the determination of antimony; the tin phosphate retained traces of antimony even after repeated washings with ammonium nitrate or dilute tartaric acid solution, and traces of tin made their appearance in the filtrates. It was also found that a mixture of tin and antimony, unlike an alloy of these metals, did not dissolve in the mixed acids. Henz's method (this J.,

1904, 133) whether worked as described by Fresenius, or by any of the modifications favoured by other chemists, was found to be the most accurate and rapid method for the determination of antimony and tin. The following points of detail are, however, worthy of note:—(1). Sulphuric acid should not be substituted for *aqua regia* as the solvent of the mixed metals; (2), the amount of potassium sulphide must be reduced to a minimum; (3), an excess of hydrogen peroxide is essential to the success of the operation; (4), the antimony sulphide may be dried at 280° C. in an atmosphere of carbon dioxide; and (5), the tin may be deposited electrolytically by the employment of rotating electrodes.—W. P. S.

Bismuth: Determination of — volumetrically. R. Ehrenfeld and A. Indra. Z. anal. Chem., 1909, 48, 24–26.

The solution for the determination is made with the least possible quantity of dilute nitric acid and the bismuth precipitated by adding an excess of standard sodium phosphate solution, in the cold; the liquid is then made up to a measured volume and, when the precipitate has settled, is filtered. An aliquot part of the filtrate is mixed with the quantity of ammonium acetate required to combine with the free nitric acid present, and 10–20 drops of cochineal tincture, made according to Repiton's method [boiling powdered cochineal with 100 c.c. of water for an hour, replacing the water lost by evaporation, again raising to the boiling point, and then filtering the cooled solution, after adding 50 c.c. of alcohol], are added, so that the liquid has a dull brick-red colour. The excess of phosphate is then determined by uranyl acetate solution which has been standardised against the sodium phosphate, using the same number of drops of cochineal tincture as before; as this is run in, the colour becomes gradually paler, until almost white, and then changes, rather sharply, to a dull green. In no case should the supernatant liquid appear reddish at the end of the reaction.—F. SOPH.

Uranium and vanadium: Determination of —. W. D. Engle. Eng. and Min. J., 1909, 87, 155.

The following method is said to yield results agreeing closely with those obtained by gravimetric methods and to effect a considerable saving of time. From 0.5 to 2 grm. of the ore is weighed out, care being taken that the amount of uranium in the assay does not exceed 0.25 grm. The sample is decomposed with 20 c.c. of dilute sulphuric acid (1:5) and evaporated until sulphuric anhydride fumes are evolved. If organic matter is present, nitric and sulphuric acids are used for the decomposition. After cooling and diluting to 100 c.c., the uranium and vanadium are oxidised by 3 c.c. of hydrogen peroxide and an excess of sodium or ammonium carbonate added. The solution is then boiled for a few minutes, partially cooled, filtered, and the precipitated iron washed, redissolved with dilute sulphuric acid, and reprecipitated. The solution is maintained in a highly oxidised condition by the use of hydrogen peroxide. The combined filtrates are acidified with sulphuric acid and 0.5 to 1 grm. of ammonium phosphate added. The solution is boiled to expel the carbon dioxide, uranyl ammonium phosphate being soluble in ammonium carbonate. It is then made ammoniacal, boiled, acidified with acetic acid, and filtered. The precipitate is washed with a 4 per cent. solution of ammonium sulphate which prevents the tendency of the precipitate to pass through the paper. If the amount of uranium is very small, a little aluminium sulphate should be added for the same purpose. The filtrate, which contains the vanadium, is treated with 10 c.c. of strong sulphuric acid and 2 grms. of sodium sulphite. The excess of sulphur dioxide is boiled off, and the hot solution immediately titrated with *N*/20 potassium permanganate solution. The vanadium or V_2O_5 factors are obtained by multiplying the iron factor of the permanganate by 0.9159 or 1.631 respectively. The uranium precipitate is dissolved in dilute sulphuric acid, and granulated zinc of known purity added. The reduction is continued for 45 minutes, after which the solution is decanted off and the zinc washed. The solution and washings are titrated with *N*/20 per-

manganate solution, the iron factor of which multiplied by 2.133 gives the factor for uranium, or by 2.5167, the factor for U_3O_8 .—F. R.

ORGANIC QUANTITATIVE.

Halogens; Determination of — in organic compounds. C. W. Bacon. J. Amer. Chem. Soc. 1909, 31, 49–52.

HAVING found the method proposed by Stepanoff (this J., 1907, 35) to be untrustworthy when carried out as described, the author has undertaken an investigation with the view of ascertaining the conditions under which nascent hydrogen can be relied upon to reduce organic halogens quantitatively. The method given below is the result of this investigation. About 0.2 grm. of the halogen compound is placed in a dry, pear-shaped flask. If *w* be the number of grms. of the compound taken, add 15*w* c.c. of alcohol (at least 98 per cent.) if the compound contain chlorine, or 6*w* c.c. if the compound contain bromine, or 4*w* c.c. if it contain iodine. The mixture is then heated under a reflux condenser and metallic sodium is added through the condenser; this operation should extend over at least 30 minutes. A total of 19.5*w* grms. of sodium are added if chlorine be present, 8.5*w* grms. in the case of bromine, or 5.5*w* grms. in the case of iodine. The mixture is boiled for 1 hour longer (this is essential), cooled to about 50° C., diluted through the condenser with cold water, acidified with nitric acid, an excess of silver nitrate added, and the excess then titrated according to Volhard's method. If the halogen involved be chlorine, the silver halide is removed by filtration before titrating; otherwise, filtration is unnecessary.—W. P. S.

XXIV.—SCIENTIFIC & TECHNICAL NOTES

Solvate theory; Present status of the —. H. C. Jones. Amer. Chem. J., 1909, 41, 19–57.

IN the present paper is given an account of the more important facts established, and of the more important conclusions reached, as the result of investigations on the nature of solutions extending over 10 years, and of which detailed descriptions of the various steps have been published at intervals. A relation between the amount of water of crystallisation of a substance and the extent of the

depression of the freezing point of water caused by such substance holds for a large number of compounds and is strong evidence for the existence of complex hydrates in aqueous solutions. The existence of hydrates accounts for the facts: (1), that the minimum in the boiling-point curve occurs at a greater concentration than the minimum in the freezing-point curve of aqueous solutions of a given substance; (2), that the temperature at which a substance crystallises is lower, the larger the amount of water of crystallisation it contains; and (3), that there is a connection between the hydrating power of ions and the temperature-coefficients of their electric conductivity, those ions with the greatest hydrating power having the largest temperature-coefficients, and the more dilute solutions, containing more complex hydrates, having larger temperature-coefficients than the more concentrated solutions. There is evidence of the same general character for the existence of solvates (analogous to hydrates) in non-aqueous solutions. Evidence in favour of the solvate-theory is also described, which has been adduced by study of the absorption spectra of solutions and the effect of one salt with hydrating power upon another salt present in the same aqueous solution and also possessing hydrating power. (See also this J., 1899, 791; 1900, 355; 1902, 1352; 1906, 563; 1908, 334.)—A. S.

Trade Report.

Proposed alteration in the French patent laws. "Times" Eng. Suppl., Feb. 3, 1909.

The Minister of Commerce has just introduced into the Chamber an important Bill dealing with the working of patents.

Under the existing law the owner of a patent is compelled to undertake the working of it within a period of three years from the date of application, with the penalty of forfeiture of his rights for non-compliance with the Act. The patentee must carry out his invention in France, but the Act does not clearly define what must be the nature of the working of the patent, and hence it is easy to evade the provisions.

The proposed amended patent law involves the sacrifice of all rights conveyed under the patent in the case of a patentee failing to carry out his discovery or his invention in France within a period of three years dating from the day on which he deposits his application, or who shall have discontinued the working of his patent for three consecutive years, unless he shows justifiable cause for the interruption of the work. Forfeiture is likewise decreed in the case of a patentee who carries on the working of his patent exclusively or almost wholly on other than French soil, or who, after a sufficient time has elapsed (as the Law Courts may determine), fails to show that his patent has been worked in France, or in the colonies, on a sufficiently extensive scale. Similar provisions are laid down in the case of models and designs.

The Bill also specifies that modifications may be introduced subsequently arising out of diplomatic agreements which may have the effect of imposing strict reciprocity between the two contracting parties.

Proposed new French Customs tariff.

The Customs Commission of the French Chamber of Deputies have recently issued their Report, in which recommendations are made for the amendment of certain sections of the French Customs tariff. The proposals have yet to be dealt with by the French Legislature, and may be substantially altered as the result of further consideration. A translation of the proposals in their present preliminary form has just been issued as a Parliamentary Paper, and those portions of the tariff in which no alteration is proposed are also included, and the present rates of duty are added for comparison.

Copies of the Return may be obtained at the price of 1s. per copy, either directly or through any bookseller, from Messrs. Wyman and Sons, Ltd., London, E.C.; Messrs. Oliver and Boyd, Edinburgh; or Messrs. E.

Ponsonby, Dublin. In ordering, the reference number, Cd. 4489, should be quoted.

Less than 1% "		

* Including tax to cover supervision of soda factories.

† Plus Indirect Tax on alcohol used in manufacture.

‡ Not including internal Revenue Tax.

§ Ferro silicon containing more than 5% silicon.

¶ Ferro chromium containing 10% or more of chromium.

	Old Min. fr. per 100 kilos.	New Min. fr. per 100 kilos.
Tungsten, pure or alloyed with iron...	Not spec.	40.00
Molybdenum or titanium, pure or alloyed with iron	5% ad val.	100.00
Vanadium, pure or alloyed with iron	10.00	400.00
Ferro-aluminium containing 20% or more of aluminium	7.50	40.00
Iron and steel*	10.00	8.00
Copper bars		
plates:		
4 m. and less in length		10.00
Over 4 m. thick		12.00
Under 4 m. " "	10.00	
Over 4 m. in length:		
More than 4 m. thick		12.00
Under 4 m. thick		15.00
Copper wire—		
Diam. 1 mm. or more		10.00
" between 1/10 and 1/4 mm.	10.00	15.00
" under 1/10 mm.		30.00
Lead, small shot	6.50	9.00
Tin, wire	6.00	8.00
" leaves, under 1/10 mm. thick	6.00	30.00
Nickel wire, pure—		
Over 1 mm. thick	10.00	15.00
Under		18.00
Nickel wire with copper—		
Over 1 mm. thick	17.50	18.00
Under		20.00

* The alterations must be studied in the original.

New Books.

YEAR-BOOK OF PHARMACY, comprising Abstracts of Papers relating to Pharmacy, Materia Medica, and Chemistry, contributed to British and Foreign Journals from July 1, 1907, to June 30, 1908, with the Transactions of the British Pharmaceutical Conference at the Forty-Fifth Annual Meeting held in Aberdeen, September, 1908. Editor of the Year-book, J. O. BRATHWAITE. Editors of the Transactions, E. SAVILLE PECK, M.A., and EDMUND WHITE, B.Sc. J. and A. Churchill, 7, Great Marlborough Street, London. 1908. Price 10s. 6d.

Svo volume, containing 537 pages of subject matter, 336 of abstracts, etc., and 201 of Transactions. Indexes of names and subjects close the work. The Transactions include a list of members of the British Pharmaceutical Conference, and of the Officers, Council, etc.

THE MECHANICAL APPLIANCES OF THE CHEMICAL AND METALLURGICAL INDUSTRIES. A complete description of the Machines and Apparatus used in Chemical and Metallurgical Processes for Chemists, Metallurgists, Engineers, Manufacturers, Superintendents and Students. By OSKAR NAGEL, Ph.D. Published by the Author, New York. 1908. VACHER & SONS, Great Smith Street, London, S.W. Price \$2.00, or, 8s. 6d. net.

Svo volume, containing 302 pages of subject matter, with 292 illustrations, and an alphabetical index of subjects. The subject matter is classified in the following groups:—I. General. Covering. Packing. Expansion-joints. Valves. Steam-traps, etc. II. Steam and water power. III. Gas power. IV. Electric power. V. Transportation of solids. VI. Transportation of liquids. VII. Transportation of gases. VIII. Grinding. IX. Mixing machines. X. Firing and furnaces. XI. Separating. XII. Purification of gases. XIII. Evaporating. Distilling, and Condensing. XIV. Drying Appliances. XV. Measurement of temperature. APPENDIX. The Works chemist as engineer.

GESÄTTIGTE-SALZLÖSUNGEN VOM STANDPUNKT DER PHASENLEHRE. Von ERNST JANECKE. Wilhelm Knapp's Verlag, Halle a. S. 1908. Price M 9.00.

Svo volume, containing 179 pages of subject matter, with 85 tables, and 153 illustrations. Classified tables

of contents in illustrations and tables, are given at the end of the work, and an alphabetical index of names of authors. The work is dedicated to the author's teacher, Prof. Dr. J. H. van't Hoff. The subject matter is classified as follows:—I. Introduction. Phase rule. II. Classification of solutions according to the phase rule. III. Saturated solutions of salts which appear in the solid phase only in the anhydrous condition. IV. Solutions in which both the anhydrous salt and hydrates appear in the solid phase. V. Solutions of two salts with similar ions, when no mixed crystals are formed. VI. Formation of mixed crystals as solid phase in saturated solutions of two salts with similar ions. VII. Solutions of a salt in basic and acid aqueous media. VIII. Solutions of three salts with similar ions, in water. IX. Solutions of four salts with similar ions. X. Solutions of reciprocal pairs of salts. XI. Solutions of reciprocal pairs of salts on saturation with a fifth and sixth salt. XII. Solutions of mixtures of salts.

GRUNDRISSE DER ALLGEMEINEN CHEMIE. Von WILHELM OSTWALD. Vierte, völlig umgearbeitete Auflage. Wilhelm Engelmann's Verlag, Leipzig, 1909. Price M. 20. (Cloth M. 21.20, Half-calf M. 22.50.)

LARGE Svo volume, containing 644 pages of subject matter with 67 illustrations, and indexes both of names and subject matter. The leading themes and general classification are as follows:—BOOK I. MATERIALS. (i), Laws of conservation. (ii), Forms. (iii), Heat phenomena of gases, and the first law of energy. (iv), Liquids. (v), Solid bodies. BOOK II. STOICHIOMETRY. (vi), Equivalents and combining weights. (vii), Gay Lussac's law. (viii), Dilute solutions. (ix), Chemical constitution. BOOK III. CHEMICAL THERMODYNAMICS. (x), Thermochemistry. (xi), Chemical kinetics. (xii to xiv), Chemical equilibria (a), of the first order; (b), of the second order, and (c), of the third and higher order. BOOK IV. ELECTROCHEMISTRY. (xv), Electrolytic conduction. (xvi), Ions. (xvii), Electrolytic equilibria. (xviii), Voltaic cells. (xix), Electrolysis and polarisation. BOOK V. MICROCHEMISTRY. (xx), Theory. (xxi and xxii), Special microchemistry. (xxiii), Kinetic theory of gases. BOOK VI. PHOTOCHEMISTRY. (xxiv), Radiant energy. (xxv), Chemical action of light. (xxvi), Radio-activity, etc. BOOK VII. CHEMICAL RELATIONSHIP. (xxvii), Methods. (xxviii), Stoichiometrical relationships.

HISTOIRE DU DÉVELOPPEMENT DE LA CHIMIE DEPUIS LAVOISIER JUSQU'À NOS JOURS. Par A. LAZENBURG. Translation of the 4th German edition. By A. CORVISY. Librairie Scientifique A. Hermann et Fils, 6, rue de la Sorbonne, 6, Paris. 1909. Price 15 frs.

LARGE Svo volume, containing 375 pages of subject matter, with alphabetical indexes of names, and table of contents. The work is classified as to subject matter according to the following scheme:—I. Phlogiston theory, and its overthrow. II. Change of ideas as to combustion. Priestley, Scheele, Lavoisier. III. Chemical nomenclature. IV. Richter's researches. Dalton's atomic theory, etc. V. Electrochemical theory of Davy. Gay Lussac's law of volumes, etc. VI. Berzelius' chemical system. Dulong and Petit. Proust. Dumas' determination of vapour densities. VII. Organic chemistry and its beginnings, etc. VIII. Theory of radicals. IX. Graham on phosphoric acid. Liebig on acids generally etc. X. Influence of Gmelin's school. Theory of residues. Polybasic acids. XI. Divisibility of the molecules of the elements. Williamson. Polyatomic radicals. XII. Mixed types. Kolbe and Berzelius. Polybasicity, etc. XIII. Idea of types. Quadrivalence of carbon. Specific volumes, etc. XIV. Theory of aromatic compounds. Quinones. Industry of dyestuffs, etc. XV. Fundamental ideas of chemistry. Phenomena of dissociation. Thermochemistry. Photochemistry. XVI. Law of mass action. Phase rule. Solutions. Liquid air, etc. XVII. Study of radium. New conception of valency. Solid solutions. Allotropy. Suboxides and peroxides. Catalysis. Chemistry of colloids.

STRAITS SETTLEMENTS, REPORT OF THE RESIDENT-GENERAL OF THE FEDERATED MALAY STATES FOR 1907. [Cd. 4471.] Wyman and Sons, Fetter Lane, E.C. Price 3d.

THIS publication contains a copy of the annual report for 1907 of the Resident-General of the Federated Malay States.

REPORT ON THE TRADE IN IMPORTS AND EXPORTS AT IRISH PORTS DURING THE YEAR ENDED 31ST DECEMBER, 1907. [Cd. 4429.] Wyman and Sons, Fetter Lane, E.C. Price 1s.

IN this report (the fourth) a considerable advance has been made in the completeness of the returns, and it may be taken that the tables given represent within 1 or 2 per cent. of the gross quantities of Irish imports and exports.

POISONS AND PHARMACY ACT, 1908. [8 Edw. 7, Ch. 55.] Price 1½d.

SECTION 2 relates to the sale of poisonous substances exclusively for horticulture and agriculture, and Section 5 to the labelling of sulphuric, nitric, and hydrochloric acids, soluble oxalates, etc.

Patent List.

Where a Complete Specification accompanies an Application, an asterisk is affixed. The dates given are (i) in the case of Applications for Patents, the dates of Application, and (ii) in the case of Complete Specifications Accepted, those of the Official Journals in which acceptances of the Complete Specifications are advertised. Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

I.—PLANT, APPARATUS, AND MACHINERY

APPLICATIONS.

1381. Hunt. *See under VII.*

1530. Sparks. Cooling granular, pulverulent, and like material. Jan. 21.

1599. Ges. f. Kunst. Zug, and Schwabach. Conveying gases.* Jan. 22.

1626. Rose. *See under II.*

1650. Delporte. Agglomerating or hardening finely-divided or friable substances. Jan. 23.

1659. Webb and others. *See under X.*

1716. Suero. Manufacture of filters.* Jan. 23.

1719. Wallis. Pipette. Jan. 23.

1726. Beaven and Lancaster. *See under XVII.*

1781. Pages, Camus, et Cie., and Bardy. Pulverising, spreading, and mixing fluids. [Fr. Appl., Jan. 27, 1908.]* Jan. 25.

2049. Fawcett, Preston, and Co., and Shield. Evaporating apparatus. Jan. 28.

2101. Bramwell. Filtering apparatus.* Jan. 28.

COMPLETE SPECIFICATIONS ACCEPTED.

1455 (1908). Black and Lennox. Continuous drying machines. Jan. 27.

4491 (1908). McNeil and McNeil. Apparatus for drying, roasting, etc., pulverulent or granular material. Jan. 27.

4861 (1908). Bousfield. Pycnometer. Jan. 27.

7879 (1908). Winder. Non-conducting coverings for steam boilers, etc. Jan. 27.

9669 (1908). Clark and Krenl. Filters. Jan. 27.

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

1247. Zailer. Manufacture of peat products for fuel.* Jan. 18.

1248. Novel Combustible mixture for explosion motors. [Swiss Appl., July 2, 1908.]* Jan. 18.

1261 and 1262. McMullen. Power gas producers. Jan. 18.

1284. Ely. Apparatus used in the manufacture of gases. Jan. 19.

1484. Dempster and Sons, and others. Gas retorts. Jan. 21.

1626. Rose. Exhaustion of metal filament lamps and other apparatus requiring a high vacuum. Jan. 22.

1629. Lewes. Incandescent mantles. Jan. 22.

1630. Milbourne. Gas purifiers. Jan. 22.

1866. Bansart. Regenerative coke ovens.* Jan. 26.

1882. Pilgrim and Pilgrim. Gas generators.* Jan. 26.

1890. Glasgow. Manufacture of water gas. [U.S. Appl., Nov. 20, 1908.]* Jan. 26.

1928. British Thomson-Houston Co. (General Electric Co.). Electric lamp filaments. Jan. 26.

1937. Dempster and Sons, Ltd., and Brooke. Gas retorts. Jan. 27.

2027. British Thomson-Houston Co. (General Electric Co.). Manufacture of electric arc electrodes. Jan. 27.

2028 and 2029. British Thomson-Houston Co. (General Electric Co.). Manufacture of electric lamp filaments. Jan. 27.

2413. Davis. Gas washers. Jan. 28.

2292. Blau. Production of liquid illuminating gas. [Ger. Appl., Jan. 31, 1908.]* Jan. 30.

COMPLETE SPECIFICATIONS ACCEPTED.

19,659 (1908). Thompson (Von Inwold and Von Inwold). Manufacture of incandescent filaments for electric lamps. Jan. 27.

23,806 (1908). Manger. Transforming alcohol for use as fuel. Feb. 3.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, PETROLEUM, AND MINERAL WAXES.

APPLICATIONS.

1708. Knottenbelt. Treatment of petroleum, rock oils, etc.* Jan. 23.

1858. Royley. Treatment of shales. Jan. 26.

IV.—COLOURING MATTERS AND DYESTUFFS.

APPLICATIONS.

1227. Newton (Bayer und Co.). Manufacture of azo dyestuffs and process of developing them on the fibre. Jan. 18.

1244. Johnson (Badische Anilin und Soda Fabrik). Manufacture of colouring matters of the pyrazolone group. Jan. 18.

1245. Johnson (Badische Anilin und Soda Fabrik). Manufacture of azo dyestuffs. Jan. 18.

1397. Newton (Bayer und Co.). Manufacture of azo dyestuffs. Jan. 20.

1600. Newton (Bayer und Co.). Manufacture of dyestuffs of the galloxyanine series. Jan. 22.

1816. Johnson (Badische Anilin und Soda Fabrik). Manufacture of azo colouring matters. [Addition to No. 25,311 of 1908.]* Jan. 25.

2290. Act.-Ges. f. Anilinfabr. Manufacture of sulphurised dyestuffs soluble in water. [Ger. Appl., Feb. 10, 1908.]* Jan. 30.

COMPLETE SPECIFICATIONS ACCEPTED.

13,499 (1908). Stephan and Rahtjen. Producing compounds of α -isatinanilide and its homologues with sulphurous acid. Jan. 27.

16,207 (1908). Durand, Huguenin, et Cie. Manufacture of leuco derivatives of anilides of gallocyanines or their sulpho-derivatives. Jan. 27.

19,793 (1908). Ges. f. Chem. Ind. in Basel. Manufacture of chlorinated derivatives of indigo. Jan. 27.

V.—PREPARING, BLEACHING, DYEING, PRINTING, AND FINISHING TEXTILES, YARNS, AND FIBRES.

APPLICATIONS.

1227. Newton (Bayer and Co.). *See under IV.*

1291. Gottlieb. Decoration of textile and like fabrics. [Addition to No. 24,913 of 1905.]* Jan. 19.

1375. Rothwell-Jackson and Edge. Device for circulating liquids through bleaching kiers, etc. Jan. 20.

1407. Luxberg. Producing threads of artificial silk. Jan. 20.

1774. Ashwell. Recovering caustic soda from the weak solutions resulting from mercerisation of cotton, etc. Jan. 25.

1920. Fowler. Dyeing, and dyes for use therein. Jan. 26.

2313. Heimann. Treatment of fabrics.* Jan. 30.

COMPLETE SPECIFICATIONS ACCEPTED.

1265 (1908). Guadagni. Production of artificial silk. Jan. 27.

8302 (1908). Sperry. Preparation of silk dyers' products. Jan. 27.

8393 (1908). Payne and Wallace. Dyeing machines. Jan. 27.

12,253 (1908). Guadagni. Machines for producing artificial silk threads. Jan. 27.

15,015 (1908). Boullier and Lafais. Manufacture of artificial silk. Jan. 27.

23,725 (1908). Gallati-Grob. *See under XII.*

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

1381. Hunt (Love). Lixiviating apparatus particularly for extracting sodium nitrate from caliche. [Addition to No. 7007 of 1906.]* Jan. 20.

1424. Wakefield. Treatment of calcium carbide. Jan. 20.

1585. Carulla. Manufacture of ammonium salts and iron oxide from ferrous liquors. [Addition to No. 27,302 of 1908.] Jan. 22.

1735. Schmidt. Dissolving silica direct from natural silica and silicates. Jan. 25.

1844. Poulsen. Utilisation of gelatinous silica. [Comprising in No. 491, Jan. 8, 1909.] Jan. 26.

2007. Simpson and Oviatt. *See under X.*

2010. Fuchs. Production of magnesium compounds and calcium carbonate from dolomite. Jan. 27.

2071. Clacher. *See under XI.*

2109. Giana. Converting salts of tribasic phosphoric acid into salts of pyrophosphoric acid. [Ital. Appl., June 30, 1908.]* Jan. 28.

COMPLETE SPECIFICATIONS ACCEPTED.

1842 (1908). Johnson (Badische Anilin und Soda Fabrik). Production of titanium-nitrogen compounds. Jan. 27.

3428 (1908). Dyes (Hempel). Manufacture of formic acid. Jan. 27.

10,522 (1908). Carrara. Preparation of zinc chloride. Jan. 27.

14,824 (1908). Soc. Commerciale du Carbone de Calcium. Fixation of phosphoretted hydrogen. Feb. 3.

19,988 (1908). Hoyermann. Removing superphosphates from a decomposition chamber. Jan. 27.

VIII.—GLASS, POTTERY, AND ENAMELS.

APPLICATIONS.

1319. Thomas. *See under IX.*

1918. Oppermann (Hitecock). Manufacture of sheet glass.* Jan. 26.

2294 and 2295. Sadamon, Grace, and Exploration Co., Ltd. Preparation of china clay. Jan. 30.

COMPLETE SPECIFICATION ACCEPTED.

11,321 (1908). Grünzweig and Hartmann. Impregnating ceramic and like porous objects. Jan. 27.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

1319. Thomas. Kilns for making bricks, tiles, pottery, etc. Jan. 19.

1477. Davis. Making raw material bricks for the production of Portland cement clinker in stationary kilns. Jan. 21.

1849. Best. Manufacture of heat-insulating materials. Jan. 26.

2250. Stephenson. Kilns for burning bricks and tiles. Jan. 30.

COMPLETE SPECIFICATIONS ACCEPTED.

1339 (1908). Bonnefort. Manufacture of artificial stones. Jan. 27.

15,625 (1908). Snyder. Manufacture of cement. Feb. 3.

24,325 (1908). Albon and Parker. Manufacture of firebricks. Feb. 3.

X.—METALS AND METALLURGY.

APPLICATIONS.

1332. Kuzel. Manufacture of metal filaments. [Ger. Appl., Feb. 22, 1908.]* Jan. 19.

1339. St. Laurent and others. Manufacture of aluminium alloys. Jan. 19.

1365. Barclay and Rodgers. Impts. in German silver. Jan. 20.

1403. Bryant and Ivinson. Solders for metals and alloys. Jan. 20.

1404. Bryant and Ivinson. Treatment of metals and alloys. Jan. 20.

1485. Dauncey and Donne. Extraction of metals from ores. Jan. 21.

1519. Parnell. Treatment of ores. Jan. 21.

1639. Webb and others. Smelting, melting, or heating metals, ores, and other substances. Jan. 23.

1677. Goodland and others. Apparatus for recovering the metallic contents of ores, etc. Jan. 23.

1703. Ingram. Blast furnaces. Jan. 23.

1786. Boulton (Kroeschell Bros. Co.). Crucible furnaces.* Jan. 25.

1789. Horwood. Separation of zinc blende and other constituents from ore concentrates and slimes.* Jan. 25.

1791. Braey-Laurent and Moritz. Furnaces for roasting pyrites and other ores. [Fr. Appl., June 3, 1908.]* Jan. 25.

1882. Sulman and Durant. Treatment of metalliferous ores or compounds. Jan. 26.

1887. Reynolds. Manufacture of steel. Jan. 26.

2007. Simpson and Oviatt. Reduction of metallic oxides, sulphides, and carbonates. Jan. 27.

2192. Sebillot and Maclaure. Treatment of ores with sulphuric acid. [Fr. Appl., Jan. 29, 1908.]* Jan. 29.

COMPLETE SPECIFICATIONS ACCEPTED.

1582 (1908). Birkbeck (Just Mining and Extraction Co.). Cyanide process for extracting precious metals from ores. Feb. 3.

12,383 (1908). Churchward. Production of alloyed steels. Jan. 27.

13,888 (1908). Fennell and Sackett. Manufacture of articles of wrought iron, mild steel, and their alloys. Feb. 3.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

APPLICATIONS.

1340. St. Laurent and others. Secondary batteries. Jan. 19.

1345. British Thomson-Houston Co. (General Electric Co.). Aluminium electro-lytic cells. [Comprised in No. 18,619 of 1908.]* Jan. 19.

1425. Hutchins. Insulation of electrical conductors. Jan. 20.

1436. Dolphin. Obtaining copper and other metals by the electrolytic process, and septa for separating solutions. Jan. 20.

1448. Newlands, Eastick, and Rouse. Making an electrolyte to facilitate carriage of the same. Jan. 21.

1503. Marino. Treatment of wood for use in accumulators. Jan. 21.

1879. Walter. Electrolytic cells. Jan. 26.

2071. Clacher. Purifying carbon for electrical and other purposes. Jan. 28.

2127 & 2128. British Thomson-Houston Co. (General Electric Co.). Electrical insulating material.* Jan. 28.

2216. Centrals, f. Wissensch.-Techn. Untersuchungen. Producing long voltaic arcs. [Ger. Appl., Feb. 1, 1908.]* Jan. 29.

COMPLETE SPECIFICATIONS ACCEPTED.

1470 (1908). British Thomson-Houston Co. (General Electric Co.). Electric furnaces. Feb. 3.

8425 (1908). Evans (Elektrochem. Werke). Production of electrical discharges. Jan. 27.

12,634 (1908). Keller. Electric furnaces. Feb. 3.

28,147 (1908). Gibbs. Electrolytic cells. Jan. 27.

XII.—FATTY OILS, FATS, WAXES, AND SOAPS.

APPLICATION

1550. Justice (Mills and Battle). Extraction of oil from oleaginous material such as seed.* Jan. 21.

COMPLETE SPECIFICATIONS ACCEPTED.

11,121 (1908). Imbert. Preparation of emulsifying agents. Feb. 3.

23,725 (1908). Gallati-Grob. Production of a fluid washing and bleaching compound. Feb. 3.

XIII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, &c.

(A.)—PIGMENTS, PAINTS.

COMPLETE SPECIFICATION ACCEPTED.

6584 (1908). Hannay and Wilson. Manufacture of a white sulphate of lead pigment. Feb. 3.

(B.)—RESINS, VARNISHES.

APPLICATION.

1990. Geuthe. Manufacture of linoxyn, etc., especially for making linoleum. [Ger. Appl., Feb. 26, 1908.]* Jan. 27.

COMPLETE SPECIFICATIONS ACCEPTED.

23,005 (1908). Linoleum Manufacturing Co., and others. Manufacture of floorcloths, wall coverings, etc. Feb. 3.

23,039 (1908). Terrisse. Treatment of hard and semi hard copals and preparation of varnishes. Jan. 27.

(C.)—INDIA-RUBBER.

APPLICATION.

1888. Bloxam (Callender). Manufacture of indiarubber or analogous material. Jan. 26.

XIV.—TANNING, LEATHER, GLUE, SIZE, &c.

APPLICATION.

1865. Lehmann. Preparation of colourless glue.* Jan. 26.

COMPLETE SPECIFICATION ACCEPTED.

22,368 (1908). Leconte. Preparing hides for the manufacture of leather. Jan. 27.

XV.—MANURES, &c.

COMPLETE SPECIFICATION ACCEPTED.

19,902 (1908). Lake (Amer. Bacteria-ized Fertiliser Co.). Fertilisers. Jan. 27.

XVI.—SUGAR, STARCH, GUM, &c.

APPLICATION.

2219. Wynberg and Wynberg. Treatment of sugar cane and sugar cane waste.* Jan. 29.

COMPLETE SPECIFICATION ACCEPTED.

8699 (1908). Goldschmidt. Treatment of the juice of potatoes. Feb. 3.

XVII.—BREWING, WINES, SPIRITS, &c.

APPLICATIONS.

1269. Melhuish. Treatment of malt liquors. [Addition to No. 13,528 of 1908.]* Jan. 18.

1726. Beaven and Lancaster. Furnaces of malt and other kilns and drying apparatus. Jan. 25.

2202. Charmat. Fermenting, clarifying, and drawing-off apparatus for effervescing liquids. [Fr. Appl., Feb. 1, 1908.]* Jan. 29.

COMPLETE SPECIFICATION ACCEPTED.

13,528 (1908). Melhuish. Priming of malt liquors. Feb. 3.

XVIII.—FOODS; SANITATION, WATER PURIFICATION; AND DISINFECTANTS.

(A.)—FOODS.

APPLICATIONS.

1342. Weck Ges. Sterilising apparatus. [Ger. Appl., Jan. 20, 1908.]* Jan. 19.

1444. Rittmann (Herdeen). Flour. Jan. 20.

2202. Charmat. See under XVII.

COMPLETE SPECIFICATION ACCEPTED.

6438 (1908). Desmaroux. Sterilising liquids of organic origin. Jan. 27.

(B).—SANITATION; WATER PURIFICATION.

APPLICATION.

1239. Wilton. Treatment of sewage and materials therefor. Jan. 18.

COMPLETE SPECIFICATION ACCEPTED.

10,557 (1908). Ives. Treatment of sewage. Jan. 27.

(C).—DISINFECTANTS.

APPLICATION.

1238. Wilton. Disinfectants. Jan. 18.

XIX.—PAPER, PASTEBOARD, &c.

APPLICATIONS.

1715. Galay and Galay. Air-proof and waterproof paper and films.* Jan. 23.

1874. Gray and Moore. Making paper waterproof and semi-transparent. Jan. 26.

COMPLETE SPECIFICATION ACCEPTED.

8708 (1908). Lilienfeld. Manufacture of cellulose derivatives from viscose. Feb. 3.

XX.—FINE CHEMICALS, ALKALOIDS,
ESSENTIAL OILS, AND EXTRACTS.

APPLICATIONS.

1431. Kalle und Co. Production of substances for conferring on human beings and other animals immunity against disease. [Ger. Appl., March 24, 1908.]* Jan. 20.

1560 and 1561. Wellcome and Barger. Production of physiologically active bases. Jan. 22.

1984. Newton (Bayer und Co.). Manufacture of pharmaceutical compounds. Jan. 27.

2020. Fritzsche und Co. Manufacture of *n*-propyl ester of *p*-aminobenzoic acid. [Ger. Appl., March 24, 1908.]* Jan. 27.

COMPLETE SPECIFICATIONS ACCEPTED.

7319 (1908). Bentley, Weizmann, and Clayton Aniline Co. Treatment of liquid pinene hydrochloride and production of solid pinene hydrochloride and camphene. Feb. 3.

§ 14,408 (1908). Zimmermann (Chem. Fabr. auf Aetien, vorm. E. Schering). Manufacture of bornyl oxalate. Jan. 27.

XXI.—PHOTOGRAPHIC MATERIALS AND
PROCESSES.

APPLICATION.

1498. Sonnenberg. Photographic plates, films, papers, etc. Jan. 21.

COMPLETE SPECIFICATIONS ACCEPTED.

23,615 (1907). Clifton and Wells. Colour photography. Feb. 3.

1689 (1908). Caldwell. Production of sensitised surfaces for photography. Jan. 27.

18,750 and 20,909 (1908). Brasseur. Manufacture of screens for colour photography. Jan. 27.

21,839 (1908). Verein. Kunstseide Fabr. Making colour screens for photography, etc. Jan. 27.

XXII.—EXPLOSIVES, MATCHES, &c.

COMPLETE SPECIFICATIONS ACCEPTED.

1677 (1908). Sparre. Manufacture of explosives. Jan. 27.

9259 (1908). Kynoch, Ltd., and Udal. Wrappers for blasting explosives. Jan. 27.

Journal of the Society of Chemical Industry.

No. 4, Vol. XXVIII.

FEBRUARY 27, 1909.

No. 4, Vol. XXVIII.

Birmingham Section.

*Meeting held at Birmingham University on Thursday,
November 5th, 1908.*

MR. HENRY SILVESTER, B.Sc., F.I.C., IN THE CHAIR.

THE UNIVERSITY TRAINING OF INDUSTRIAL CHEMISTS.

BY HENRY L. HEATHCOTE, B.Sc.

(Abstract.)

At the Annual General Meeting of the Society of Chemical Industry in Birmingham in 1907, Sir Oliver Lodge, the Principal of the University, speaking about the Department of Applied Chemistry, said: "We have not yet attacked the building for Applied Chemistry, and really Applied Chemistry seems so enormous and portentous a subject that I really don't know how to begin. Perhaps some ideas will be suggested in this meeting as to what we ought to do." The Committee of the Birmingham Section thought that a paper on the subject would lead to a discussion that might throw some light on the question of how applied chemistry may best be taught at Universities.

Having gone through the mill myself, I was anxious to do something to guide those who are striving to fit themselves for the work of an industrial chemist. I also hoped that something might be said which could be applied by those whose business it is to conduct commercial undertakings, for chemistry lies at the very core of all schemes for the welfare of the manufacturer, and of commerce generally.

First of all the industrial chemist must be a sound chemist, and any considerable departure from the full degree course of the University would impair this. He wants all the theory he can get. Theory is a labour-saving device in every sense of the word, and the sounder the man be in theory the fewer futile experiments will he make, and the more efficient will he and his laboratory be. A degree stands not for so much knowledge, but as a mark that the owner has developed to a high degree the mental machinery for obtaining and handling information in an efficient manner. So all industrial chemistry should be post-graduate, and I propose to limit myself to suggestions respecting post-graduate work. If any alteration has to be made in the graduate course, we may leave suggestions for the making of it to those whose special business it is to produce scientists.

In the post-graduate work of the applied chemist we should have lectures and much laboratory practice in a great variety of commercial materials and products—finished and unfinished—their composition and properties being ascertained by chemical, physical, and mechanical tests, and their uses illustrated during the lectures, mention being also made of their sources, prices, and any special restrictions to their carriage or use. This knowledge is the basis of all industrial chemistry, be it the construction of new plant or the improvement of an old process. We must certainly not restrict the materials to those employed in and produced by local industries, but it would be well to see that as many as possible of them were included.

Having dealt with commercial materials, we might have a lecture course with some laboratory practice in the processes of industrial chemistry, such as transporting solids, liquids, and gases; weighing and measuring; grinding etc.; melting, dissolving, emulsifying, and absorbing; cleaning, washing, drying; heating and cooling; evaporating and distilling; crystallising and dialysis; separating solubles and insolubles; electrolysis; oxidation and reduction; precipitation and prevention of recipitation. This course might well be mainly descriptive, and on the lines of Grossmann's little book, "The Elements of Chemical Engineering," might give accounts

of the large scale equivalents of the laboratory Bunsen, the beaker, the filter, the blowpipe, the U tube, the burette clip, etc. The object of this course would be to make the student acquainted with the items of plant that are common to many industries, and to show him what "plant" is. No attempt would be made to study a number of the large aggregates of plant that characterise the several chemical industries; perhaps one or two which illustrated important chemical, physical, or economic achievements might be briefly described. In the laboratory he should handle these items of plant sufficiently to acquire a mental grasp of the construction and purpose of the appliance and its parts. Manual dexterity should not be expected. In this way he will learn by experience some of the differences between small and large scale appliances, and in the lectures differences in the results produced when passing from the small to the large scale should be carefully examined and explained. This will familiarise the student with some of the difficulties that meet the experimenter who is trying to reduce a new process to practice on a commercial scale and facilitate this generally difficult and tedious change.

In accordance with the principle of keeping costs well to the front in the mind of the student, he should learn the approximate cost and sources of these items of plant, and also the cost of the plant required for producing definite chemical and physical changes. In this part of the course the student will have already met some of the forms of power. In the next part he should make a special study of the chemical, physical, and mechanical effects of power on commercial materials. He should learn the cost of the various kinds of power. The special advantages of each and the consumption of power in producing definite chemical and physical changes should be calculated and classified. All this might be taught in the Department of Industrial Chemistry.

In the engineering department he should learn the form and purpose of a number of tools and appliances used in engineering, how to read blue prints, and make rough drawings. He should be able to calculate and ascertain the stresses and strains in simple structures—should, in fact, go through an elementary general engineering course, including the strength and testing of materials and simple structures.

This information is not to equip him for working plant or for designing or constructing machines or structures, but because, as a chemist, he will require it. The industrial chemist in a works corresponds to the special senses in a human being. The engineer corresponds to the muscular and kinæsthetic senses which serve a purpose very different to that served by the organs of predication. Consequently we must select courses so as to steer clear of producing anything like the chemical engineer.

In the department of metallurgy the student might be familiarised with the microscopical examination of metals and alloys, and in the physics department with calorimetry and pyrometry.

In the department of commerce the industrial chemist must learn something of industrial economy, the statics and dynamics of the social organism: wealth, and its production, value, price, costing, selling, plant, tools, maintenance, depreciation, and the factors that influence it, the relations of employers to employed, and the law relating to employment.

The final course in the applied chemistry department might well be aimed to develop the faculty of synthesis, and might include lectures on "Invention," a study being made of improvements and patents. This course could be run in conjunction with research on an industrial problem. This should be drawn up so as to bring in as many commercial considerations as possible to exercise the student in their practical synthesis and acquaint him with the sources of information. If the research is one likely to end in patent specification so much the better. It is neither necessary nor advisable for the future industrial chemist to pursue research in pure chemistry; in

that the purity of the product would be one of his chief aims, whereas the chief concern of the industrial chemist is the applicability of his product.

Professor Kipping, in his address to the Chemical Section of the British Association, appears to favour the pure chemist with some knowledge of chemical engineering, and probably many will prefer this combination so long as the plant required does not have to be bought by the University. To my mind, however, it is much better to study existing commercial products and processes thoroughly well before attempting to improve on them. With his suggestion that temporary scholarships might be founded for special research work I heartily concur. This system is at work, not only at the University of Kansas, but also in that of Illinois, where there are several from \$250 to \$500; and in Michigan, where there is one for gas research and one for pharmaceutical research. But this should follow after courses in industrial chemistry. Furthermore, the product would be much of a specialist, and although, as we all know, specialists are often useful and successful men, yet a University is not the place for producing specialists—the two ideas are fundamentally opposed. The only condition which might serve as an excuse for specialisation to suit particular industries is when one or more industries is dominant in the district and has absorbed a great amount of capital and labour. Not until any one industry, by reason of its special bequests or special development, earned the right to special attention from the University could there be any chance, in my opinion, of chemical plant of a special character being added at the University's expense. The dominant chemical industry in the Birmingham and Midland district is iron and steel making, and the University Metallurgy Department already contains special plant, which is worked by the students and a few experienced workmen under Professor Turner and his assistants. The other chemical industries in this district are acid and alkali manufacture, phosphorus and chlorates, cyanides, varnishes and pigments, tar and ammonia distillation, pharmaceutical preparations, enamel, gas manufacture, soap and explosives, leather tanning, glass making, pottery and porcelain making, electro-plating, and brewing, no one of which is dominant. This fact, to my mind, is a final argument against further specialisation at present, and furnishes another reason for making the training a broad one.

It is important, however, to face this question of specialisation from every point of view. A University is not only a teaching institution, but it is supposed to further the knowledge of the subjects it deals with. Precisely how this idea will be worked out in the case of a Department of Applied Chemistry it is hard to predict, but it is quite possible that in some cases the knowledge desired will only be obtained if the process or product in question is studied on the commercial scale. The need for this would become apparent in the course of a research, and it seems that the directions for specialisation would be a natural outcome of the research work of the department. From the point of view of expense it is clear that the amount invested in items of plant would be as small as possible. Some items of plant are necessary in order to neutralise the cramping effect of tremulously handling fragile beakers and chasing the minutest particle of some precipitate, to educate a delight in moving something worth moving and getting a really good yield though the melting point may be a trifle low. The student should use plant until he feels himself to be master of it, and every part his ready servant.

There are many Universities, Technical Colleges, etc., that have Departments of Applied Chemistry not organised on these lines. I felt it my duty to make myself acquainted as far as possible with the courses and equipment of such departments both at home and abroad, but however interesting it would be to give some account of their methods, I feel convinced that every locality must consider its own special needs and not follow any precedents till after careful study of its own requirements.

These other Departments of Applied Chemistry seem to fall naturally into three main classes according to the main product aimed at, viz., the pure chemist, the works

chemist, and the chemical engineer. It is particularly interesting to note how institutions of the extreme types are tending to become more like the middle type. Birmingham University is an example of the one change, and as an example of the other the Massachusetts Institute of Technology, in 1903, abolished certain options in their course of chemical engineering and decided to make it essentially a course of chemistry, with some work in applied mechanics and mechanical engineering. Another recent change in that Institute is the transfer of instruction in industrial chemistry from the third year to the fourth year.

The works is not the proper place for a chemist to acquire all his knowledge of industrial chemistry. It is altogether too hard on the student to expect him to prove satisfactory under these conditions. Professor Kipping has recently pointed out the disastrous results that have attended this policy. The University seems in every way a suitable place for the prospective applied chemist to study his profession; there the change from pure chemist to works chemist can be made as gradual as is necessary; there he can pass gradually from laboratory appliances to their large scale equivalents. These fundamental industrial appliances, processes, and materials can be represented to him as the "elements" of industry. When certain of these combine they go to form one industry; when others combine another industry is formed, and so on. Visits to works can be made into an exercise in "analysis" and analogous exercises in synthesis could be performed. What he has to learn about economics could be introduced in a similar way. For instance, the phenomena of supply and demand for commercial commodities have their counterpart in the phenomena of solution, diffusion, and crystallisation. The solubility and rate of diffusion regulate the "supply" of solid to a liquid or medium capable of taking it up. The higher the temperature the more rapidly will—as a rule—the solution be effected, and the more rapid the rate of travel the quicker are letters and goods carried and the sooner the demand for a commercial commodity is met and supplied. The phenomena of supersaturation have their counterpart in over-production, and its results and so on. In the works he will get no such kindly tuition. At the University, too, he is near the other departments of learning that he should attend. At the same time, it should be possible at any rate in Birmingham for much of the analytical work to be done in the fine laboratories of the Municipal Technical School and perhaps for other courses to be elaborated there, and duly recognised as qualifying for graduation or other University privileges.

Now, in conclusion, is this programme, which is dictated by considerations both general and local, feasible? It has been said that no man exists so versatile as to properly direct a department like that I have sketched. It has also been suggested that the best way is to employ outside experts. There are obvious advantages in bringing experts into touch with the University, but, if we wish to avoid specialisation, it would be better to do without specialists, and try to instal a Professor, Assistant Professor, or director as the permanent head and organiser of all the courses. It would not be very difficult to find the right man; he is not expected to be an expert in all departments of applied chemistry. And if there is no such man it does not alter the fact that if this is the right kind of department a man must be found to direct it. When an article that is in great demand cannot be bought on the market, the manufacturer makes it himself if he really wants it. The University should make sure that it knows what kind of man is wanted, and then—if not forthcoming—select the most promising material and mould it—or set it to make itself—into the required finished product.

Comments on extract from foregoing paper.

Professor R. MELDOLA: In substance I agree generally with your proposals. In fact, I had, during the vacation, been making rough notes of my ideas before I knew of your intention to read this paper, and it is most interesting to me to find how far our views coincide.

Professor W. A. TILDEN: (1) The establishment of departments of applied chemistry in the colleges and

Universities will not improve the situation in England to any appreciable extent until the manufacturers generally are prepared to employ scientific chemists and pay them adequately. A man of ability will not spend five or six years in study at his own expense unless there is a career for him in prospect at the end of it. Too many of the so-called "chemists" in works are people of inferior education and ability, who would, in most cases, take a low place in any profession, say, medicine, law, or engineering. To attract ability in the direction of applied chemists, it must be made known generally to the public that this is a field in which at least a living can be made.

(2) I disapprove of attempts to imitate industrial apparatus in a college. The whole of the conditions under which work can be done are so different that the expense is not justified. This opinion, however, does not exclude the idea of giving instruction in mechanical drawing, properties of constructive materials, the principles of the steam engine, the dynamo, and the methods of handling large quantities of solids, liquids, and gases. But a student will get more useful information from a visit to a gas works or vitriol works than he would derive from an attempt to work a charge of material, say, 1/100th of commercial dimensions under conditions in which cost and kind of labour, etc., cannot be measured, and in apparatus which may become antiquated in a year or two.

(3) It is futile to expect any University or college to turn out chemists ready to play a leading part in all kinds of chemical industries. The man who, for example, knows all about soap might be useless in a cement works or an explosive works. The man who is likely to be most useful must be a man of natural ability, who has given five years at least to mathematics, physics, chemistry and elementary applications of mechanics and electricity. At the end of that time he will be prepared to undertake the special study which can only be undertaken when he has decided what department of chemistry he is going into. This can best be done in connection with the industry itself, and here the manufacturer who intends to use scientific assistance ought to step in and having found the well trained chemist take him into the works and teach him the business as is done in Germany and to some extent in America.

(4) Of course every well educated man should have a certain knowledge of book-keeping and business methods. But this is essentially the work of the business manager and not of the chemist. If the latter is to be employed in the study of markets and economic questions he cannot be expected to do anything in the way of improvement of processes and manufactures in which he is interested. His place should be in the laboratory, or when in the works he should be associated with the engineer, with whom he should work in harmony.

Sir WILLIAM RAMSAY: In this country no settlement has occurred for two reasons:—Few, if any, works employ a sufficient number of chemists, and few, if any, allow their chemists to know what goes on. In Germany works draw their chemists from two sources—Polytechnika and Universities. In the former an attempt is made on the broad lines you indicate, to give young men a suitable training. Such young men, however, are not found to be equal in ability or capacity to the product of the Universities. The reason stated is that though Polytechnika students are well informed as to what has been done, they do not know how to tackle new problems; or if they try to do so, their energies are directed to attempting small improvements in detail. The German University student, as everyone knows, is trained in research; he learns a method of thought, and can easily substitute a practical for a theoretical problem. Anyhow, I have been told that the University man commands a larger initial salary than the Polytechnikum man, and as a rule gives more satisfaction in the long run.

The student in Germany gets his training in the works. I have been told by one who employs 150 chemists, that they sort themselves rapidly into three classes:—(a) the routine men, who like to spend their time over analyses. These check the raw material and the

finished products. They are quite happy in doing this class of work. These are the most numerous. (b) The research chemists, who try new processes, suggested by themselves or others. (c) The managers of departments, or foremen who prefer to direct the manufacture and keep the hands up to their work. The Polytechnika men belong mostly to the first class; some to the third. The University men to the second, mostly; a good many to the third.

It would be possible to give a complete technical training in a University only if the man were to devote, say, 10 or 15 years of his life to being trained. By that time, he would probably be unfit for any post. Far better stick to science, to learn the methods of thought and of work; if the man has it in him, he will soon pick up the commercial and technical sides. I could give you numerous instances where pure scientific chemists are making large sums or receiving large salaries; their works experience lasted perhaps a year or two years.

Mr. THOMAS TYLER: Chemical technology cannot be taught on any sufficiently practical scale in a University like Birmingham, though particular branches of technology can be very efficiently illustrated, and a few—very few—demonstrated. All research sooner or later tends to practical application. There must be autoclaves, presses, filters (vacuum and pressure), compressed air, and even high pressure steam, with sufficient electrolytic appliances to investigate the fruitful field opening in that direction. But these are aids to the development of what after all is the instinct of practicality. I know well trained men of high scientific accomplishments who have been and are in works laboratories, but whom I would rather pay to do nothing than place in charge of works. No man is fit to be a technical chemist, in the true sense, unless he is grounded in the principles of chemistry, physics, elementary mechanics, metallurgy, electricity, mathematics, geometry (and drawing), and botany. A technologist must not be ignorant of German and French, particularly German. With these departments of science plus common sense, you probably have your man minus experience, and no University will give him that.

Mr. G. S. ALBRIGHT: The man who is valuable in a works must have the soundest possible knowledge of the various branches of pure science—the more the better—-but especially, of course, chemistry, physics, mathematics, and mechanics. His knowledge should be such that he can tackle any investigation set before him from various aspects, and if he has not the information at hand in all cases he should know where to look for it.

The more he has seen of the working out of industrial operations the better—one transfer of a laboratory process to a works scale if watched by an intelligent man will go far to make him into a useful chemist. He should have learnt how to properly set down and index all his work and to keep clear records and make out cost sheets. He must be honest, honourable, and reliable—the labour and research of years are embodied in practical chemical processes and are a very portable asset; hence the hesitation of many manufacturers to admit students into their works.

As to the amount of practical training which a University can give, much more might be done to give a trained chemist some insight into the difficulties of practice. Probably after graduation he should spend at least a year in studying the history of chemical processes, with their successes, and especially their failures and the causes for the failures—assisted possibly by a museum of specimens of the products and of the materials used in the construction of chemical plant.

On the practical side all that is wanted is a "crèche" laboratory where certain processes could be put through on the 1 cwt. scale. A course would consist of one or two processes carried through from the laboratory into the crèche, with minute attention to the differences in apparatus and appliances necessary—quantities, times, temperatures, all noted, and conclusions drawn from the crèche work all finally embodied in a cost sheet, showing probable labour, fuel, repair of plant and raw materials, &c.

A few comparatively simple processes which involved

boiling either with or without pressure, filtration, evaporation, drying, furnacing, and such like would give the student a real insight with some of the difficulties of practice and show how often means and operations which are easy at the Laboratory are difficult outside and sometimes *vice versa*. Here the student becomes familiar with the conversion of laboratory into practical commercial quantities and volumes—a most useful art.

In addition some knowledge of engineering drawing and the getting out of quantities is about all the equipment which a University can expect to give, except where a special industry is dominant, such as dyeing at Bradford or Leeds, where the *crèche* is on a small scale and can be specialised.

PROFESSOR A. SMITHELLS: I am strongly of opinion that there is room for a type of University teaching which shall concern itself with the borderland knowledge which lies between formal science and the craftsmanship of chemical industries.

PROFESSOR H. R. PROCTER: One of the conclusions to be drawn from your paper is that no one method of teaching industrial chemistry is applicable to all industries. While I can imagine that a miniature blast furnace would yield no useful information, it is quite certain that small sized plant in other industries is capable of giving useful results, or why would it be so common in some trades for manufacturers themselves to have small experimental installations? The object of a University technical department should be not to supersede practical experience in the works, which is essential; but to teach things which the works in the particular trade cannot teach. In a teaching laboratory many small scale experiments can be made which are impossible on a manufacturing scale, and while, in the works, investigations, however interesting, are merely pursued to the stage of immediate profit, it is possible in a scientific laboratory to carry them further with ultimately yet more important results. The greatest obstacle to technical teaching is the attitude of the manufacturers themselves, who ask for a training which must take at least 5 years, and will only pay the wages of an ordinary skilled mechanic. Under these circumstances prizes are so few that the more promising young men will not take the technical side.

DR. G. H. BAILEY: A *rapprochement* between University authorities and industry is urgently called for in the interests of both, and the main difficulties will vanish when once it is fully realised that University teaching is incomplete without its practical bearings and that industrial chemistry rests for its support on the kind of teaching which the University should afford.

As an illustration of the importance of this attitude of mind, the following is my own experience:—I have lectured for many years on sulphuric acid and alkali as an optional subject for the degree in the Honours School of Chemistry at the University. Notwithstanding that of all special subjects I considered this (and do still) the most suitable, I became impressed with the undesirability of training the industrial chemist by means of a special course. I therefore proposed over 20 years ago to substitute general chemical technology of engineering and practice in analysis and operations of a suitable nature according to the syllabus quoted in an address to the Manchester Section of the Society in 1905. The working out of such a course was a very arduous undertaking, but I carried it through two evening sessions, 1888 to 1890. It met with appreciation on the part of the many engineers and chemists who attended it, and I pressed for its adoption as a substitute for, or a supplement to, the special course in sulphuric acid and alkali for day students. The proposal met with no support from the authorities, who failed to realise that such a training was called for.

MR. EUSTACE CAREY: The technology of some industries can be learnt to a much greater extent in the laboratory than is possible in other industries. The large scale operations cannot be learnt and practised otherwise than in the works, and the only method of procedure is for a chemist to be employed in the laboratory at the commencement of his career with any firm. In a short time, he is naturally, as soon as opportunity offers, placed in charge of some practical branch of the business; it

may be to pioneer in something new, which has been initiated in the laboratory, or to take charge of some department which is already established. The latter course, in my own opinion, is much the better for the young chemist. In short, practical technology can only be learnt by practice in the works.

MR. A. SOUTHALL: The product of such a system of training as that described should prove valuable in almost any chemical industry, provided that: (a) The subject of it did subordinate all to the question of profit and loss. (b) The subject did not acquire contempt for the implements and apparatus he would have to employ on the large scale which are not usually comparable with the elaborate appliances available at Universities. (c) The proposed course insisted on accuracy in chemical analytical work.

In the special branch of pharmaceutical chemistry, the manufacturer selects the most promising material and moulds it, or sets it to make itself into the finished product.

PROFESSOR T. GRAY: The course of study which you suggest seems to me very good; it is, in fact, very similar to that followed in this college. Our aim is to give the student a general knowledge of the principles of engineering which will enable him to appreciate the engineer's point of view, and this, I understand, is your proposal. To ask the student to take a complete engineering course in addition to his chemistry course would be quite useless, and even if students could be induced to spend the necessary time the results would not be satisfactory. The addition of the subjects you mention to the ordinary University course in the form of post-graduate work would probably cause the least inconvenience; but in colleges such as ours, where all the students intend to adopt an industrial career, I think it an advantage to introduce the engineering element at an earlier stage. The students should know something about drawing, mechanics of structures, prime movers, and sources of power before they attend the applied chemistry courses. In order to permit of this without taking too much time away from their principal studies we have extended the diploma course to four years. In the first year the students have engineering drawing three hours weekly, and mechanics two hours weekly. In the second year mechanics three hours weekly; and in the third, motive engineering two hours weekly. These classes form an addition to the usual chemistry, mathematics, and physics courses. In the third year lectures on general technical chemistry are given. These take up materials of construction of plant, from a chemical point of view; water for industrial purposes; fuels and their applications; and the various industrial operations, such as grinding, mixing, separation of solids, etc., evaporating, distillation, etc., with examples chosen from different industries. In the fourth year the time is divided between the pure chemistry and applied chemistry laboratory. In the latter they work through exercises on sampling and analysis of gases with the well known forms of apparatus; pyrometry by calorimetric, thermo-electric, electrical resistance, heat and light radiation methods, including standardisation; calorimetry by different methods, including the use of the bomb and gas calorimeters; exercises with experimental gas producer; tests of efficiency of combustion of boiler furnace with calculation of various heat losses; exercises with filter press; separation of solids by settling and filtering *in vacuo*; evaporation, including multiple effect evaporation, for which we have a small plant with 40 sq. ft. heating surface; refrigeration; crystallisation. The object is to teach students how to make the necessary experiments, with quantities of substance from a few lb. up to a cwt., which form the preliminary stage in the development of a new process. So far as possible the experimental plant is on the model of that used on a large scale industrially. We have now under consideration the addition of a course in economics, but so far nothing has been done in this important department.

DISCUSSION.

The CHAIRMAN said that the training of industrial chemists in the past had frequently formed the subject for

addresses and discussions by the Society of Chemical Industry, and the evolution of so complicated an organism as Mr. Heathcote had described justified, he thought, the considerable amount of attention the topic had received. Within the last eighteen months there had been a revival of interest in the relation of science to industry. Professor Meldola, in his address to the Chemical Society, which was widely circulated, devoted a considerable portion of it to the influence of the more recent institutions upon chemical industry, and the autumn address of Professor Kipping to the British Association, in which he dealt with similar questions, would be within the recollection of all. The views put forward in those addresses, together with those expressed by Mr. Heathcote and his correspondents, pretty well covered the ground to be discussed. All were agreed that a sound scientific education must be the basis of the training of an industrial chemist, and it was only in the post-graduate course where a marked divergence of opinion existed. On the one hand it was argued that familiarity with operations on a large scale would give a practical bias to the mind of the student, and enable him more readily to apply his science to industrial practice. Quite recently he had occasion to compare the old calendars of some of our Universities and colleges with the more recent ones, and he was struck with the provisions that are now made for courses in subjects that Mr. Heathcote stated to be desirable. For instance, in Birmingham University experience could be obtained by intending industrial chemists in the testing and managing of boilers, gas engines, producers; analyses of gases; measurement of high temperatures; ammonia plant, blowers, etc. Drawing: The reading and making of drawings of plant of a type found in chemical works, etc. Materials used in various structures. The testing of the strength of materials, etc.; hydraulics, etc. A number of Universities and colleges had provided facilities of a similar kind, and if these opportunities were not largely taken advantage of it must be reluctantly attributed to the lack of demand on the part of manufacturers for such a product.

On the other hand, it was argued that the post-graduate course should be largely devoted to original research, for such a training induced originality of mind and resourcefulness, and from such an education new processes and valuable modifications of old ones would be much more likely to result. The Universities were quite capable now of supplying either type of man, and the real difficulty was that there were so few openings to reward a student at the end of a rather expensive training. More co-operation between the Universities and industry was desirable, and the discussion of the subject by the meeting would, he thought, help in that direction. A better understanding would result in a wider field of work for the trained chemist, and that would favourably affect both education and industry.

Professor FRANKLAND said that industrial chemistry was the making of money out of chemical processes, and the industrial chemist was the man who could do that. The possession of any other qualities was quite immaterial; as long as one could make money out of chemical processes one was a successful industrial chemist. They ought to be quite clear as to the kind of industrial chemist they were considering from an educational standpoint. They were, he thought, all agreed that he was to be an industrial chemist of the highest order. In many chemical industries there were many so-called chemists employed who were doing useful work in their way; but who were not true "industrial chemists." He fully agreed with Mr. Heathcote when he said that he did not propose that any of his suggested industrial departments should interfere with the training in pure chemistry which such a future industrial chemist would receive. There could be no doubt that the industrial chemist must be fully equipped with the knowledge of the general principles of chemistry; and he agreed that the more he knew of such general principles and the greater his theoretical attainments the greater use would be to the industrial concern he joined or directed. In this matter of ideal education they were always confronted with a most formidable difficulty: the length of time which a student was prepared to devote to his

studies. After an experience of many years, he could tell them it was with the greatest difficulty that students could be induced to remain three years at a University. They wanted to be earning money, and may be, to marry, at an age which was not consistent with spending more than three years at a University. Most of those who had to do with the teaching of pure chemistry knew that the duration of student life was much too short. No proper grasp of chemical science could be obtained in the course of three years even by students of considerable ability; still less by the great majority of the students. On that account he was at present engaged on a scheme, the object of which was to provide a four years' course of study at the University; four years in which the B.Sc. degree could be obtained. All industrial chemistry would have to come after: it would have to come after the four years' course which led to the B.Sc. degree had been completed. He thought that no diminution in the amount of purely chemical training should be admitted. Three years was the minimum. He hoped that nothing less than that would be admitted by any University; indeed he trusted that the period would be extended to four years so far as chemistry was concerned. A rearrangement of the subsidiary subjects for the B.Sc. degree might be permitted. The calendar of the Birmingham University showed what had been the result of considerations of that kind.

Professors Brown, Turner, Burstall, Dixon, and himself had elaborated a scheme of study in the Birmingham University which they believed would form a suitable subsidiary subject to students who were contemplating taking the B.Sc. degree, in chemistry, as the principal subject. They proposed that students should take as a subsidiary subject a number of engineering matters such as had been referred to by the chairman. They thought that was permissible because the subjects selected from the engineering syllabus were not matters of purely utilitarian importance, but subjects which expanded the mind. They were all probably agreed that there should be this undisturbed study for the pure science degree. Then the differences of opinion arose. Some favoured a post-graduate general course of industrial chemistry; others objected to this; while there were yet others who were in favour of a special course in some selected branch of industrial chemistry. In respect to this matter his mind was not crystallised; though he would point out that at the University they had proceeded, so far, on the idea of a specialised course. They had two separate departments of applied chemistry: the brewing department and the metallurgical department. It was interesting that those two departments had been developed by their professors on entirely different lines. As to the use of plant there appeared to be great difference of opinion. In Professor Turner's metallurgical department, they saw chimneys, furnaces, and wheelbarrows and such things characteristic of works; but in the brewing department they would not see anything suggestive of either beer, wines, or spirits. A temperance party might be taken into that laboratory without fear of anything being seen connected with intoxicating liquors. He did not profess to know which was the proper way to conduct such training. He imagined, however, that what was suitable and necessary in one branch of applied science, might be unsuitable and unnecessary in another; and he had no doubt that each of his two colleagues was doing his work in the best possible way. Similar differences would doubtless be found in other branches of applied chemistry. He had no sort of objection to the creation of a Chair of Applied Chemistry provided that it would be a post-graduate subject. He could imagine that it would be an interesting and stimulating class to attend. He did not think the question of value raised by Mr. Heathcote a difficult matter. Students did not think much of value, because they were not paying for their education. When a man was engaged in an industrial concern he had to think about value, because if he did not produce paying results he would be dismissed. A man placed in a position of responsibility soon appreciated what value was. The man who could undertake the duties of this Professor of Applied Chemistry, if he were to teach general applied chemistry in the manner indicated

by Mr. Heathcote, would be a very rare bird indeed, and one difficult to catch.

If he was to be specially trained for the position, as Mr. Heathcote suggested, then he ventured to think that the "reversible reactions" by means of which he was to be made would, before his training was complete, have led to his undergoing a considerable amount of decomposition.

Mr. GEORGE CADBURY, Junr., said the ways in which chemistry might be applied in their particular case had been unfolded in a marvellous way. Of course, they bought all kinds of raw materials. With regard to the training of men, he thought it would be impossible to specialise in all the trades in which chemists would be engaged. He supposed the scope in certain trades was small; and that only a limited number of men could be engaged. It would, of course, be too much to ask the University to lay itself out to teach all those classes of chemists.

The list read out by the Chairman showed what a large variety of operations there were carried on in the Birmingham neighbourhood. The training should be of a broad character, in which those taking it should be able to appreciate the special difficulties of the industry into which they were going. The training should be such that they could tackle difficulties as they arose, and solve them in their own way. The most successful training would be that which enabled men to adapt themselves to circumstances. Adaptability was one of the chief things which should be brought out. He was not sure that that was included in Mr. Heathcote's formula. Perhaps an elementary knowledge of economics was as good a training in that as anything. What was needed to be done was to train men who would be able to tackle problems and deal with men. They had their directors to deal with, and it was essential that they should make their own points clear in simple language—not always in formula—and get on with those who were to carry on the processes they initiated. He foresaw great difficulties if they were going to specialise on any particular trade. The amount of plant required would be enormous, and there would be the danger of the knowledge imparted quickly becoming out of date. In all processes and trades the advance was rapid, particularly in the processes used; and it would be almost impossible for a professor or a department to keep up to date. On broad lines he favoured a general training, which would develop the character of men, and enable them to tackle their own special difficulties when they got into their own special line of work.

Dr. PRICE said that what chiefly impressed him in the paper was the prolonged period of time which would be necessary for an industrial chemist to spend before he got a training of the kind which Mr. Heathcote desired. It must, they understood, be a post-graduate course, that was, after 3 years, or better still, 4 years' training for a science degree; in this matter he was in agreement with Professor Frankland. He must then obtain a knowledge of the many subjects which it had been suggested it was necessary for the industrial chemist to know, which meant that he had got to spend several years in obtaining such knowledge without apparently getting time for research. It seemed to him to be absolutely necessary for the industrial chemist to have some training in research. He was sure that Mr. Heathcote, who was looked upon as a successful industrial chemist, owed his success largely to the training that he himself had in research. It was only after one had had such a training that he would be able to overcome the difficult problems which he might meet with in his every-day work. If they took a student who had gone through the ordinary University course and simply taken his degree, he very much doubted if he would be able to surmount some unexpected difficulty without a great deal of trouble. An industrial chemist of the highest type must be capable of original investigation; and if he first came into contact with such investigations in the works laboratory it was so much time wasted for the employer before he had gained the necessary experience; it seemed to him that such knowledge should be obtained if possible in

the post-graduate course. Suppose they had this course, would the manufacturers help adequately towards the better training which such a course represented? Co-operation in carrying out the curriculum was of the utmost importance. In his department at the Birmingham Municipal Technical Schools there was a very successful class in gas manufacture. Up to two sessions ago the class was taught by an engineer, and naturally the importance of chemistry was not emphasised. A change was then made, the class being divided into two sections, the one consisting of engineering and the other of chemistry. He believed in having a teacher to conduct such classes who was not only a capable chemist, but one who also had an intimate knowledge of the actual works methods. Possibly owing to the fact that gas making is a municipal undertaking here, he was able to secure the services of Dr. Davidson, the chief chemist at the Corporation Gas Works; and the classes were very successful. For this session he desired to arrange another industrial course, in connection with acid and alkali manufacture, with a teacher who possessed a proper works experience, as well as thorough scientific knowledge.

Mr. H. HOLCROFT thought Mr. Heathcote's proposal undesirable at the present time. The numbers of the unemployed were already too great. Presumably the chemists to be specially trained were intended to be employed in the British Isles, although the proposal did not state so definitely. If so, then he knew he was expressing the opinions of many manufacturers who could possibly increase their staff of chemists, that it was unwise to extend their business in this country in view of the unfavourable economic conditions prevailing, when compared with the position of foreign competitors. He could claim some little knowledge of the subject from the business side; and had discussed the question thoroughly with personal friends, chemists in this country and from the Continent, and had come to the conclusion the matter should be decided from the economic and business standpoint. It was only this consideration which would weigh with the bulk of manufacturers. Their object was clear—they wanted reasonable security for their capital and an adequate return as interest on their money. He also attributed want of success on the part of the manufacturers either now or in the past, not to their ineptitude or any want of skill on the part of British chemists, but to the fault of the prevailing economic conditions. He instanced the coal tar industry, and said the same skill and knowledge which was responsible for the birth of the industry was undoubtedly competent to develop it to the highest point, especially with the advantage of being first in the field, if economic conditions had not stood in the way. The new Patent Laws might possibly do something to lessen the inequality and place the British manufacturer in a better position to compete, but much yet remained to be done.

Mr. A. E. TUCKER submitted that it was common knowledge among manufacturers that University training was not one necessarily resulting in the best chemist; and he thought this must be so, because the personality of the men so immensely influenced the result. Again, it was a matter on which there was common agreement that there were many highly successful and highly scientific men occupying important positions in all branches of industry who had never studied at a University. He knew several such in the Birmingham district. He desired to question Mr. Heathcote's proposition that theory was a labour-saving axiom; in his experience the old maxim that "an ounce of practice, etc." still held. Mr. Heathcote must have seen, like himself, important practical results in works which had been obtained by experience alone and which were not amenable to any ordinary theory, and indeed were sometimes opposed to theory. He could give instances in which this proposition was true. As to a Chair of Industrial Chemistry, if by this was meant the inclusion of the multifarious branches of industrial chemistry, he regarded such a recommendation as altogether beyond the range of practical politics. The industrial chemist, so called could not be taught outside the works, these should be his University and any attempt in establishing small

industrial plants in Universities would, he believed, prove highly costly and quite unsuccessful.

Dr. R. S. MORRELL said there was one suggestion he wished to make, and if adopted he thought it would help to clear up the difficulty of the application of University research to the wants of the manufacturer. Research might be made of more immediate use to the manufacturer if there were a closer connection between works chemists and the University. Speaking from experience, he found that there was much pure laboratory work to be done which could be well carried out in the University. The work would be good training in research for a post-graduate student in his second year. The results would have no direct money value—they could only be useful in the hands of a works chemist, who with his knowledge of industrial conditions could turn them into £ s. d. Such a scheme of research would enable the manufacturers to encourage research scholarships and fellowships, and would eliminate the feeling that there was a danger of disclosing trade secrets by so doing. It might be asked, "How much of the research work done in the University would be of practical use or application in this generation?" He feared it would be far too little. He did not think that the manufacturer would ever allow the student, and much less the professor, to have the run of the "works"; but he thought he could influence University research through the suggestions of his works chemist so that results might be obtained which would be of value to the present generation.

Mr. E. A. LEWIS was of opinion that applied chemistry could only be taught by applied chemists, and that every University should have a lecturer on the chemical and metallurgical staff with at least 10 years' works experience. Many teachers had an idea that if their students passed examinations they were competent chemists. Theoretical examinations might be necessary, but examinations in practical chemistry were a waste of time, being no test whatever of competency in applied chemistry. When an employer engaged a young chemist he required to know if he was an accurate worker during the whole of his college career, not during a few hours in an examination, he also wanted to know if he could think in tons. In many colleges the estimation of impurities in commercial products was never taught, and yet an employer was often more interested in the traces of impurity present than the principal constituents. The art of sampling was usually ignored altogether, although in many commercial laboratories it was as important as analysis. The granting of degrees or diplomas after a 3 years' course of training was wrong; no degree or diploma for technical chemistry or metallurgy should be given except after 5 years' works experience or for some original research on applied chemistry. He agreed with Mr. Heathcote that analyses of commercial materials should be practised. A large amount of applied chemistry could only be learnt by practical experience in a works.

Mr. HEATHCOTE, in reply, said Dr. Price and Professor Frankland had touched upon the main difficulty—the question of time necessary for such a course as he suggested. His attitude was that some training in industrial chemistry was necessary, and he assumed that as his major premise. In this, pure chemistry was necessary; and after that he placed research, and then as much of the general training that one could get in in the time available. The trend of the Chairman's remarks was to point to the lack of openings for University-trained industrial chemists. While he (the speaker) admitted the truth of all that the Chairman said, he felt it true—and a truth that should always be associated with the admitted lack of demand—that the cure for the defect lay with industrial chemists themselves. They and they only could prove the value of their abilities and it was for them to increase the availability of their information and express it in such terms and in such places that it could reach and be understood by manufacturers. If they found by experience that their training had not been quite the most suitable, it was for them to voice their requirements and hope for the sympathetic attention of the Universities and other educating institutions. He was glad that Professor Frankland had no objections

to express, other than time considerations, to the scheme outlined in the paper. Professor Frankland did not think the question of value a very difficult one. He (the speaker) had found it a very complicated one. A man placed in a responsible position might soon come to appreciate what "value" is, but that would be no reason for neglecting to study it, and its far-reaching issues, in the preparatory training. Economic conditions were referred to by Mr. Holcroft as the obstacle to the development of the coal tar industries here. This is generally admitted as one cause, but another and greater one was the departure of Hofmann for Germany because the salary offered him in England was not sufficient. He took it that Mr. Holcroft did not intend to suggest that economic conditions in the British Isles were sufficiently malign to render the training of industrial chemists undesirable. No doubt the conditions were temporarily detrimental in some chemical industries, but not in all. Furthermore, where capital had been extensively invested in chemical plant it became all the more desirable to employ a research chemist, because, on account of the activity among scientific workers, the rate of depreciation of chemical plant was apt to be very high.

Mr. Tucker doubted whether theory is a labour-saving device. He (the speaker) supposed that each strongly advocated the food he was brought up on. It would be the height of folly to advocate neglect of theory in the training of industrial chemists. Theory was the offspring of practice. Practice comes first, and when sufficiently grown and extensive to show the rules and regularities running through it, "Theory" follows—as a rule—and probes beneath the skin of fact to get to the foundations and structures upon which facts or phenomena are superposed. He believed that in attempts to initiate new practices the first thing was to ensure sound foundations, and theory was needful for this. At the same time the "ounce of practice" which knows nothing of theory ought to be used, for it often embodied wide and long experience. He heartily concurred with the suggestion of Dr. Morrell. University professors certainly had the precedent of inanimate nature when they, like the trees of yore which buried the results of their chemical activities in the earth, expended their energies now for application many centuries hence. It cannot be said, however, that this post-dating of the draft commends itself to one's common sense. Let men who excel only in this kind of work do it by all means, but do not encourage them to engage the youthful, eager, and adaptable minds of the students in like pursuits.

In conclusion, he would like to say that there must be a considerable subconscious demand for applied chemists in the engineering trades which bulk so large in and around Birmingham. If one cycle firm could employ a staff of eight in their research laboratories and keep them continually busy, there must be other industries, not usually included under the heading of chemical industries, in which chemists could do valuable work.

London Section.

*Meeting held at Burlington House on Monday,
February 1st, 1909.*

DR. J. LEWKOWITZ IN THE CHAIR.

GUNCOTTON AND ITS MANUFACTURE.

BY COL. SIR FREDERIC L. NATHAN, R.A.

Guncotton was discovered early in 1846 by Christian Friedrich Schönbein, at Bask. It was not until forty years later that it fulfilled his expectations, referred to in a letter from him to Faraday, dated the 25th August, 1846, "of becoming a dangerous rival to gunpowder," as regards its use as a propulsive explosive. Schönbein came to England in August, 1846, and was present at Woolwich on the 9th October of that year when some

successful experiments were made with his guncotton, and immediately afterwards, he, together with Böttger, who independently discovered guncotton shortly after Schönbein, entered into negotiations with Messrs. John Hall and Son, of Faversham, for the manufacture and sale of guncotton in England. This firm erected a guncotton factory adjacent to their gunpowder works, but a very disastrous explosion, on the 14th July, 1847, destroyed the factory, which was never rebuilt.

The early history of the manufacture of guncotton abroad, and of the attempts made, particularly in Austria, to adapt it for propulsive purposes in small arms and cannon, have been so fully described by S. J. von Komoeki in Vol. II. of his "*Geschichte der Explosivstoffe*," by Dr. R. Escades in "*Die Schiessbaumwolle*," and by others, that it is not proposed to deal with these matters in this paper. It is only necessary to remark that a factory was erected at Hirtenberg in Austria, where the production of guncotton on a manufacturing scale was worked out by Baron von Lenk, of the Austrian Artillery. As the general principles he elaborated with such care and perseverance are in the main those still in use, it is of interest to give briefly the general lines of his processes of manufacture. As his raw material, von Lenk employed hanks of loose cotton yarn, purified by boiling for a few minutes in a weak solution of potassium carbonate, centrifuging out the liquid, and then thoroughly washing the yarn in cold water. The cleansed yarn was dried in a hot air chamber; when dry, it was placed in airtight receptacles to cool; when cool, it was immediately dipped in the nitrating acid. The nitrating acid consisted of one part by weight of nitric acid of 1.52 specific gravity, and 3 parts by weight of sulphuric acid of 1.84 specific gravity, thoroughly mixed together and cooled. The dipping pans containing the nitrating acid were of cast iron and stood in troughs surrounded by cold water. About 6 oz. of cotton, or two skeins, were immersed in the acid at a time, and moved about in it for a few minutes, until thoroughly saturated, the cotton was then removed by means of an iron fork, placed on an iron grating above the pan, and some of the excess acid got rid of by gentle squeezing, the proportion of acid retained being about 10.5 parts by weight to 1 part by weight of the original cotton. The acid bath was made up by the addition of fresh acid after each removal. Six to eight skeins were next introduced into a stoneware pot, fitted with a lid, in which they remained for 48 hours. The pots were placed in cold water to keep their contents cool. After the 48 hours digestion the contents of the pots were emptied into a centrifugal machine and as much of the excess acid as possible extracted. On removal from the centrifugal machine, the hanks were immersed as suddenly and completely as possible in a cascade of water, washed until no longer acid to the taste, and afterwards placed in crates or perforated boxes and kept in flowing water for about three weeks. At the expiration of that time the skeins were centrifuged to remove the bulk of the water, and boiled for 15 minutes in a solution of potassium carbonate of 1.02 sp. gr. The alkaline liquid was removed, and the skeins again immersed in flowing water for a few days.

Manufacture proceeded at Hirtenberg without serious accident until the 30th July, 1862. On this day the guncotton in the magazines exploded, owing to spontaneous decomposition, and another serious explosion occurring on the 11th October, 1865, the manufacture of guncotton was officially prohibited in Austria.

Early in 1863, by the desire of the Secretary of State for War, Sir Frederick Abel took up the study of guncotton and its manufacture in this country. In his first memoir on "*Researches on Guncotton*," read before the Royal Society on the 19th April, 1866, Abel described the important steps in von Lenk's system of manufacture, mainly in connection with the production of a stable product. He was of opinion that the alkaline boiling was the most important part of the purification process, and that its function was not so much to neutralise and remove residual traces of the nitrating acid, as to dissolve unstable bodies produced by the action of the nitrating acid on small quantities of resinous and other foreign substances still retained by the tubular fibre.

The important modification introduced by Abel in the manufacture of guncotton and patented by him in 1865 (Eng. Pat. 1102), had for its object the reduction of guncotton to a pulp, and forming from this pulp grains suitable for propulsive purposes. But the "pulping" process had, he considered, a further advantage, which was described by him in the following words:—"As the difficulties attending the perfect removal of the acid with which the guncotton remains impregnated after its conversion are mainly attributable to the tubular structure of the cotton fibre, and to the circumstance that the latter contracts considerably upon conversion into pyroxylin, the complete purification of the material is very greatly facilitated by reducing the guncotton fibre to a fine state of division, similar to that of the pulp used in paper manufacture, in which form it appears likely that guncotton will receive advantageous application. By submission to the 'pulping' process, the guncotton is divided into very minute fragments, and it is at the same time violently agitated for some considerable time with a very large volume of water (rendered slightly alkaline if necessary), which is afterwards thoroughly expressed when the pulp is converted into cylinders or other forms, so that a more searching process of purification can scarcely be conceived than this disintegration of the guncotton."

It is very probable, in view of the system of purification, consisting mainly of prolonged washing in cold running water, in use at the time of Abel's introduction of the pulping process, that his treatment did produce a much purer guncotton than was formerly obtained, but recent work on the subject of the purification of guncotton has demonstrated that other points besides the complete removal of traces of the nitrating acids underlie the chemistry of the purification process. This important question will be dealt with later.

Although the pulping and granulating of guncotton did not succeed in transforming it into a propulsive explosive, the greater purity of the material resulting from the pulping process, re-established confidence in guncotton for other military purposes, such as for mines, torpedoes, and field service work, as well as for blasting purposes.

Messrs. Prentice and Co., of Stowmarket, had commenced the manufacture of guncotton according to von Lenk's system in 1863, but a serious accident occurred at this factory not long after starting manufacture. In 1865 they rebuilt and enlarged their factory and recommenced the manufacture of guncotton, introducing Abel's improvements. The Stowmarket factory now belongs to the New Explosives Company, Ltd., and is still making guncotton by the Abel process.

The manufacture of guncotton was commenced in 1863 at Waltham Abbey on a small scale under Abel's direction; it was not until 1872 that a factory capable of turning out about 250 tons of guncotton per annum was established there. The main portion of this factory consisted of old buildings which had formed part of the Saltpetre Refinery, and abutted on the principal street of the town. Fresh land, away from the town, was acquired in 1885, and a guncotton factory was built on it, and commenced work in 1890. It was considerably enlarged and altered in 1904-5, and is now capable of producing about 2000 tons of guncotton per annum by the displacement dipping process of manufacture, to be referred to later.

It has already been stated that the invention of Abel had for its object the production of guncotton in a form in which it was hoped it would be suitable for use as a propellant. To attain this object, he reduced the finished guncotton to a very fine state of division. It was subsequently found that guncotton in this condition was more readily purified than when it had to be kept in the form of skeins throughout all the processes of manufacture. Abel's process had other advantages, however. As the guncotton in its final form was reduced to a pulp, it was no longer necessary to use expensive long stapled cotton yarn, and instead of this material, waste from the cotton mills was employed; this waste cotton was, by means of suitable machinery, opened out, and in this condition it was more completely exposed to the action of the acids than were the skeins. Again, the guncotton pulp could,

by hydraulic pressure, be compressed into dense and compact masses of any desired shape, making it much more suitable for use in mines, torpedoes, and for blasting purposes, and in this condition it could be stored wet for indefinite periods. This form of compressed guncotton was rendered more valuable still when it was discovered in 1869 by Mr. E. O. Brown, of the Chemical Department, Royal Arsenal, that it could be fully detonated in its wet condition and unconfined, by fulminate of mercury.

Guncotton compressed into slabs and discs is still the form of guncotton used for mines, for torpedoes, and in connection with demolition work in the field. The processes by which these slabs and discs are produced will be dealt with later.

The von Lenk process of manufacture, as modified and improved by Abel, is universally employed at the present day, except as regards the actual process of nitration. The modifications this process has undergone will be described when dealing with this particular operation.

Before considering the actual processes of manufacture, it is desirable to say a few words about the raw materials. The base of guncotton is cellulose. The purer the cellulose, the purer the guncotton and the better the yield, other things being equal. There is little doubt that the skeins of long stapled yarn used by von Lenk were of great purity, and were free from foreign substances generally. At the same time, the fact that the skein condition was maintained in the finished guncotton made it more difficult to free it from the subsidiary products of the nitration process. This was due to the tubular structure of the cotton cellulose rendering it impossible for the purification process to remove the impurities enclosed in the long fibres. When the fibres are cut into extremely short lengths in the pulping process, this difficulty is in a great measure overcome. Cotton waste in its raw state from the mills is anything but pure; but a special industry sprang up for the purpose of converting the ordinary mill waste into a condition suitable for guncotton making. The processes it undergoes are: de-greasing by means of solvents, treatment with caustic soda, bleaching, and washing. The effect of these treatments, if properly carried out, is to produce a fairly pure resistant cellulose, and they have now been perfected to such an extent that there is no difficulty in obtaining cotton waste containing on an average not more than 0.2 to 0.3 per cent. of matter soluble in ether, and having very little altered cellulose of the nature of oxy- or hydro-cellulose. Attempts have been made to find substitutes for cotton waste equally suitable, and, if possible, less expensive. This is a matter which has received some considerable attention at the Royal Gunpowder Factory. During the last few years various materials have been investigated, and guncotton made from them on a manufacturing scale. The materials so far tested may be divided into three groups:—1. Ordinary cotton waste and weaving mill waste. 2. Short fibre from the cotton seed. 3. Fibrous materials other than cotton cellulose. As the results of experimental work the advantages and disadvantages of the three groups may be summarised as follows:—

1. *Ordinary cotton waste* from different sources varies considerably in character, and this is not without effect on the resulting guncotton. Its chief disadvantage, however, is that it generally contains considerable quantities of wood and other foreign bodies. All these substances are possible sources of regions of low stability in the guncotton. On the other hand it is plentiful, easily procured, and reasonably cheap, and it can be relied upon to produce a satisfactory guncotton as regards nitrogen-content and percentage of soluble in ether-alcohol.

Weaving mill waste is a material composed entirely of woven cotton fabric of various natures, partly broken down by mechanical means. It differs materially in character, and, as at present in the market, is liable to contain, mixed together, both soft material and hard, stiff, starchy rags. It may also be over-bleached, and contain an undue proportion of altered cellulose. In its best form it is pure cotton cellulose, remarkably free from foreign matters, and makes excellent guncotton. It is, however, apparently not procurable at present, in its best form, in anything like sufficient quantity, and its

price would probably be considerably higher than the normal price of ordinary cotton waste.

2. *The short fibre from the cotton seed*, several samples of which, from different sources, have been experimented with, would no doubt make a good guncotton, if it could be obtained freed from particles of the seed husk. Unfortunately it does not appear possible to remove the husk particles entirely by mechanical means, and the fibre is therefore subjected to a very drastic chemical treatment, which, whilst it does not remove all the husk, produces non-resistant cellulose to a considerable extent, and the final product, in consequence, gives a guncotton low in nitrogen, and with a high percentage of soluble in ether-alcohol.

3. Certain fibrous materials which, when submitted to the chlorination method of Cross and Bevan for the estimation of cellulose, were found to give a high result, were selected for experiment. Amongst these were Ramie fibre, *Marsdenia tenacissima*, to be found in certain parts of India, and *Asclepias semilunata*, which comes from Uganda. These materials contain ligneous matter, which, in the case of Ramie, is present not as an incrustation, but forming a compound cellulose with the more resistant material, and difficult to remove completely on a manufacturing scale. Even when this ligneous material has been got rid of to a considerable extent, the fibre requires a much longer nitration and boiling to produce a correct and stable guncotton. Its price also is very high. *Marsdenia tenacissima*, by a simple treatment, easily carried out on the manufacturing scale, can be made into a fairly pure resistant cellulose, giving on nitration a distinctly promising guncotton. At present, however, it is not procurable in anything like sufficient quantity, and its price is unknown. *Asclepias semilunata* can also, by a simple process of purification, be reduced to a very highly resistant normal cellulose, capable, by slightly altering the nitration process, of being converted into a guncotton similar in its properties to that prepared from cotton cellulose. So far it has not been possible to obtain this material in quantity, and its price is also unknown.

So far, therefore, the best material which has come to light for the manufacture of guncotton is weaving mill waste, if the best form could be procured in sufficient quantity, at a reasonable price. Failing weaving mill waste, cotton waste as used since the early days of guncotton manufacture still remains the best commercial form of raw material.

The nitric and sulphuric acids universally employed are commercial products of a fairly high standard of purity. It is essential that they should not contain solid impurities which might adhere to the guncotton, and which would certainly interfere with the recovery of the waste acid. Of recent years it has been possible to obtain Nordhausen sulphuric acid at a fairly reasonable price, and its use has enabled a larger proportion of waste acid to be revived than was possible when ordinary sulphuric acid only was available. It is a common practice now for explosives factories to manufacture their own nitric acid, and to revivify and recover their waste acids, and most of them possess installations of considerable size for carrying out these processes, and for mixing the two acids on a large scale. These matters hardly come within the scope of the present paper, however, even if time permitted. Before these installations existed, it was the practice to buy acids of a certain strength and mix them in the proportion of 3 parts by weight of sulphuric acid to 1 part by weight of nitric acid; now, the more correct system is being adopted of mixing large quantities, analysing the mixture, and adjusting the composition of the mixed acid by the addition of nitric or sulphuric acid, so as to obtain the correct percentage composition. The nitrating acid is, of course, made up of a certain proportion of waste acid to which new nitric acid and new sulphuric acid are added.

The manufacture of guncotton comprises the mechanical processes in connection with the preparation of the cotton waste, the chemical processes of nitration and purification, and the final mechanical operations of pulping and washing.

TEASING.

Cotton waste as supplied to the factory contains a notable percentage of hygroscopic moisture, also wood, pieces of iron, metal, string, rubber, etc. These impurities are removed as far as possible by hand picking, and the cotton is then passed through what is known as the teasing machine, which, by means of a combination of rollers, armed with iron teeth, separates the fibre of the cotton and opens out knots and lumps. As the cotton leaves the machine, it is picked over again. It was formerly the practice to cut the teased cotton in a description of guillotine into 3 inch squares. This operation was one of the features of the original Abel process, but it has been disused of late years at Waltham Abbey, because it was found that the cotton along the cut edges was felted together to such an extent as to resist the action of the nitrating acid.

DRYING.

At Waltham Abbey the cotton, as it leaves the teasing machine, is delivered on to an endless band, which carries it to the drying machine. The moisture is expelled from the cotton by a blast of hot air, supplied by a fan through a steam heater. The cotton waste passes very slowly through the machine, the operation lasting about three-quarters of an hour, and issues from it containing about half a per cent. of moisture. It is immediately weighed out into charges and placed in sheet iron boxes or other suitable receptacles with lids, to cool, for which a period of about 8 or 9 hours is sufficient. During the cooling the cotton waste re-absorbs about half a per cent. of moisture. The object of removing the moisture from the cotton waste is to prevent dilution of the nitrating acid. The above is a typical method of drying, but it is obvious that this simple operation can be effected in other ways.

NITRATION.

In von Lenk's system of manufacture the operation of nitration was carried out in two stages. The first stage was the dipping of the cotton in mixed acid contained in nitrating pans; and the second, the completion of the nitration by allowing the partially nitrated cotton to remain in contact with a weaker acid, in earthenware pots, for a prolonged time. The loss of guncotton caused by occasional decompositions in the digesting pots and the labour entailed in handling them were undoubtedly disadvantages, and led some manufacturers to revert to the even older method of completing the operation in one stage. In this system, which has been called the direct dipping process, the size of the nitrating pans was reduced to enable them to be lifted on to trucks, wheeled to the acid centrifugals and their contents tipped into them.

From this process it was but a short step to a method which has been adopted to a large extent on the Continent, and known as the nitrating centrifugal method of nitration. Instead of nitrating in pans and tipping into the centrifugal machine, the operations of nitration, digestion, and removal of the acid are all carried out in the centrifugal machine itself. In this way labour is economised and it is claimed that fewer decompositions occur and that therefore a higher yield is obtained.

It will be seen that the improvements in methods of nitration so far enumerated are of the nature of modifications of the original process such as characterise the gradual evolution of almost every manufacturing operation. The next noteworthy improvement, however, marks an entirely new departure. The inventors of the displacement system of nitration, Messrs. J. M. Thomson and W. T. Thomson, of the Royal Gunpowder Factory, Waltham Abbey, have discarded the older methods entirely, and introduced a system founded on new principles.

Before describing the displacement method, it is necessary to give a somewhat detailed account of the various processes preceding it, referred to above. It is not, however, necessary to refer to details of the earlier nitration processes, and the method of nitration used by von Lenk has been sufficiently described. The Abel nitration process, which followed very closely on the lines of von Lenk's process, was the one universally employed from about the year 1865 until comparatively modern times,

and as it is still in use in many factories both in this country and abroad, it will be described in detail as formerly carried out at Waltham Abbey.

The nitrating acid was composed of three parts of sulphuric acid of 96 per cent. mono-hydrate to one part of nitric acid of 91 per cent. mono-hydrate, thoroughly mixed and cooled. This acid was run from the store tanks into cast iron dipping pans, holding about 220 lb. each, the pans being supported in an iron tank through which cold water circulated, to keep the temperature below 70° F. The dipping pans were provided at the back with gratings, on which to press out some of the acid from the charge. The charge of cotton waste weighed 1 lb. 4 oz., and on removal from the cooling box was passed from the back through an earthenware pipe in the partition running along the back of the pans, and raked by a dipper, as rapidly as possible, into the acid. After remaining in the acid bath for about eight minutes, the cotton was removed to the grating and a portion of the acid squeezed out by means of an iron lever having an iron plate attached to one end. After a charge had been removed from the dipping pan about 13½ lb. of the mixed acid was run into it to replace the amount removed with the charge. The charge, now weighing with the adhering acid about 15 lb., was placed in an earthenware pot provided with a cover and transferred to the cooling pits, through which a stream of cold water flowed, and where it remained for 12 hours. During this period of digestion the conversion of the cotton into guncotton was completed. The contents of the pots were now emptied into a centrifugal wringing machine, and the bulk of the waste acid extracted. The guncotton was then removed from the centrifugal machine and placed in galvanised iron pans with long handles. These pans, when filled, were carried quickly across to the immersing tank and the guncotton thrown into a large bulk of water, the workmen standing by the tank and pushing the guncotton at once under the water with a stout wooden paddle. The immersing had to be done as quickly as possible, as, if the guncotton were allowed to come gradually in contact with water, it was liable to fume off. The immersing tank was fitted with a perforated copper plate, to allow the water to overflow, so that fresh water was constantly passing through the tank. The guncotton was kept well stirred by means of a wooden paddle. When 2 cwt. had been immersed, the inflow of water was stopped and the tank drained down. When all the water had been run off the tank was filled up again with fresh water. This was repeated six times or until the guncotton no longer tasted acid. When this stage had been reached the guncotton was wrung in a centrifugal machine, water from a hosepipe being turned on the guncotton for one minute during the wringing, and it was then ready for boiling.

This process, although it undoubtedly produced a good guncotton, had certain disadvantages, and the amount of labour required was very great. The plant, although individual items were not expensive, very rapidly deteriorated, and the cost of renewals and replacements was heavy. Power was required to drive the centrifugal machines, large quantities of water were used both for cooling and immersing, and decompositions, both in the pans, pots, and acid centrifugals, were by no means an infrequent occurrence.

DIRECT DIPPING.

The first attempt attended with any success to overcome some of the disadvantages of the Abel process was the introduction of what is known as the direct dipping process. This system was used on a large scale at Nobel's factory at Ardeer, in Scotland, and I am indebted to the kindness of Mr. Lundholm for a description of it, of which the following is an abstract:—

The installation consists of parallel double rows of long iron tanks known as "coolers." Iron pots termed "dippers" in which nitration is carried out stand in the coolers, 62 to each cooler. Sliding wooden covers rest on the coolers to guide the fumes from the dippers into earthenware pipes with openings at intervals, through which they are drawn by exhaust fans. The mixed acid, either cooled or warmed as necessary, is carried by lead pipes placed

between each row of coolers, and is supplied to the dippers through earthenware cocks at intervals.

Nitration.—The water in the coolers is kept at 15° C. The dippers having been placed in position in the coolers, are each filled with 127 lb. of mixed acid by measurement, from the acid taps, 4½ lb. of cotton waste are steeped in each dipper. To minimise decompositions each charge of cotton waste is added in about 10 instalments. The wooden covers are only removed to allow steeping to be done, and are then at once replaced. The temperatures of nitration are:—Initial temperature of mixed acid, 15° C.; maximum after steeping, 25° C.; temperature at end of nitration, 20° C. The duration of the nitration varies according to the output required from the plant. One, two, or three shifts may be worked per 24 hours, and the time of nitration may therefore be 24, 12, or 8 hours respectively.

The average composition of the mixed acid for a 12 hours immersion is as follows:—Sulphuric acid, 75.0 per cent.; nitric acid, 15.75 per cent.; nitrous acid, 1.30 per cent.; water, 7.95 per cent. For an eight hours immersion a higher percentage of nitric acid and less water is used; for a 24 hours immersion less nitric and more water. The average composition of the waste acid for a 12 hours immersion is:—Sulphuric acid, 77.8 per cent.; nitric acid, 11.0 per cent.; nitrous acid, 1.5 per cent.; water, 9.7 per cent.

Recovering the waste acid.—When the nitration is complete, the "dippers," covered with light aluminium lids, are placed on barrows, wheeled to the centrifugals, situated at the end of the "coolers," and the whole contents tilted out into the centrifugal. Four dippers are loaded into each centrifugal, and the guncotton having been uniformly spread round the basket, the centrifugal is run for six minutes, to remove waste acid. At the end of that time about 1 lb. of waste acid is still adhering to each pound of guncotton. The centrifugal cover, made of light aluminium, is not fixed to the centrifugal in any way, so that as little resistance as possible may be offered when there is a decomposition. This is the usual arrangement in the case of acid centrifugals. The cone of the centrifugal projects through a circular opening in the centre of the lid and is covered by a small loose aluminium box. Small holes are cut in the sides of this box, and are of service in warning the workmen when there is a decomposition, as fumes are generally seen to issue there first.

Drowning the guncotton.—When the waste acid has been removed, the guncotton is quickly lifted out of the centrifugals and thrown under the revolving paddles of the drowning tanks, which immediately immerse it. The men who do the discharging are provided with rubber gloves and wear thick flannel hoods, which completely cover the head, arms, and breast. The hoods are fitted with strong glass windows, and are connected by light rubber tubing to a supply of pure compressed air.

Prowashing.—After a given quantity of guncotton has been drowned, the water in the tanks is run off and the guncotton thrown on to draining tables forming part of the drowning tank. It is then loaded into the prowashing centrifugals, the acid water wrung out, and washed for a few minutes with cold water from a hose, to remove adhering acid. No special precautions, however, are taken to remove all acid at this stage. The bulk of the water having been removed, the guncotton is loaded from the centrifugals into bogies, and conveyed to the boiling house.

The 62 dippers in each cooler form a "charge." Eight charges are worked by each shift. The yield is 159 per cent. of dry guncotton on the dry carded cotton. The output per shift consisting of 17 men is, therefore:— $4.5 \times 159 \times 62 \times 8 \div 100 = 3549$ lb.

NITRATING CENTRIFUGALS.

The next attempt at simplifying the Abel process was one in which the nitration was effected in the acid centrifugal. A number of nitrating centrifugals have been patented, particularly in Germany, but the best known patterns are those of Messrs. Selwig and Lange, of Braunschweig.

The latest pattern is known as the "Nitrating centrifugal with acid circulation." It consists of the usual

outer casing with cover, and an under-driven rotating basket perforated with a number of holes. The machine is provided with a hinged cover with communication to an exhaust fan, and there are pipes with cocks suitably arranged for running in the nitrating acid and drawing off the waste acid. The method of working is briefly as follows:—The basket is rotated slowly, and the nitrating acid run into it and between it and the iron casing, up to about the rim. The cotton waste is introduced in small quantities at a time, and this may be done whilst the nitrating acid is running in. During nitration the basket is rotated at the rate of 20 to 30 revolutions a minute. The effect of this rotation is to cause the nitrating acid to circulate continuously through the cotton waste. On completion of the nitration the bulk of the waste acid is drawn off and the centrifugal set into rapid motion to get rid of as much more of the waste acid as possible.

According to Selwig and Lange's circular their centrifugals are now made in two sizes. The larger size nitrates 22 to 26½ lb. of cotton waste, the smaller 14½ to 17½ lb., respectively. The yield is stated to be 160 per cent. The time of a complete nitrating operation is an hour.

Messrs. Curtis's and Harvey have an installation of these centrifugals at their Dartford Works; they are of the earlier or "without acid circulation" type, and of the smaller size. Mr. MacDonald has kindly supplied me with some details in connection with their working.

The charge is 17½ lb. of cotton waste, the proportion of nitrating acid to cotton waste is 50 to 1, and its average percentage composition: nitric acid, 23.15; sulphuric acid, 69.35; water, 7.5. The nitrating operation for the production of cordite guncotton, from the running in of the nitrating acid to the removal of the guncotton, takes about an hour. The initial temperature is 15° C., the final 23° C. After extraction of the waste acid, the guncotton retains approximately its own weight of waste acid containing a fairly high percentage of nitric acid, which is lost in the immersing. Analyses of the waste acid made at Dartford, show the following mean alteration in the composition of the nitrating acid, viz., a loss of 1.70 in nitric acid, and gain of 0.91 in sulphuric, and 0.76 in water.

DISPLACEMENT PROCESS.

Guncotton has been made at Waltham Abbey by the displacement process since August, 1905. The installation consists of a number of units of 4 pans worked together. The pans are of earthenware and circular, 3 ft. 6 in. in diameter, and 10 in. deep at the side of the pan; the bottom has a fall of 2 in. to the outlet, which is three-quarters of an inch in diameter; they are supported on earthenware pedestals about 1 ft. 10 in. above the floor level. The 4 pans are connected together by lead pipes, and these are again connected to the nitrating acid supply pipe, to the strong and weak waste acid pipes, and to a waste water pipe, through a gauge-box, where the rate of flow is determined whilst the waste acids are being run off. Gravities of the acids are also taken in this box. The process proceeds as follows:—

A small perforated plate is placed over the outlet of each pan, and four perforated segment plates making a complete disc about one inch less than the inside diameter of the pan, are placed on the bottom. Aluminium fume hoods, which are connected to an exhaust fan, having been placed on the four pans, the stoneware cock on the acid supply pipe is opened, and the acid allowed to rise in the pans to the proper level. The nitrating acid is cooled in summer and warmed in winter, so as to maintain the same temperature of final nitration all the year round. The composition of the nitrating acid is 70½ per cent. sulphuric acid, 21 per cent. nitric acid, 0.6 per cent. nitrous acid, and 7.9 per cent. water; the quantity in each pan above the bottom plates is 600 lb., and below the plates is an additional 50 lb. A charge of 20 lb. of cotton waste is then immersed in the acid, handful by handful, aluminium dipping-forks being used for the purpose. When all the cotton waste has been pushed under the surface of the acid, perforated plates in segments are placed on the top of it, care being taken that all cotton waste is below the surface of the acid,

and a film of water at a temperature from 5° to 8° C. is run very gradually on the surface of the plates through

The following table gives the principal figures in connection with the four nitration processes described:—

Process.	Nature of dipping vessel.	Acids.				Quantity, lb.	Cotton waste used, lb.	Acid used per lb. of cotton waste, lb.	Time of nitration, hrs.	Yield on dry cotton waste, %.	Output per man per week, lb.
		Sulphuric acid.	Nitric acid.	Nitrous acid.	Water.						
ABEL	Cast iron pan and earthenware pot	74.00	18.00	0.60	7.40	13.75	11	11.9	12	163.75	458
ARDEER : Direct dipping	Cast-iron pot	75.00	15.75	1.30	7.95	127	41	28.2	12	159.00	1112
DARTFORD : Nitrating centrifugal	Centrifugal machine	69.35	23.15	-	7.50	800-1100	16-24	50.0	1	160.00	—

a distributor. The film of water prevents the escape of acid fumes and the fume hoods are then removed. The time required for dipping a charge is a quarter of an hour.

The nitration is allowed to proceed for 2½ hours. At the expiration of this period the cock leading to the gauge-box is opened, and the waste acid allowed to run off at the rate of about 17 lb. a minute. Water, cooled, if necessary, is run on the top of the perforated plates, through the distributor, at an equivalent rate. The major portion, amounting to about 80 per cent. of the total waste acid, is returned to the acid store tanks to be revived with Nordhausen sulphuric and new nitric acids. The composition of this waste acid is 72.70 per cent. sulphuric acid, 17.30 per cent. nitric acid, 0.65 per cent. nitrous acid, and 9.35 per cent. water. The remaining 20 per cent. of the waste acid is sent to the acid concentration factory for denitration and concentration. The quantity of acid thus dealt with amounts to about 4 lb. for every pound of guncotton. Its composition is 61.0 per cent. sulphuric acid, 17.35 per cent. nitric acid, 0.55 per cent. nitrous acid, and 21.10 per cent. water. A small proportion of the water which follows the recoverable waste acid is slightly acid to the extent of 0.1 lb. for every pound of guncotton made. This is the total quantity of acid that is lost during the process. In the direct dipping and nitrating centrifugal processes the quantity of waste acid left in the guncotton is at least equal to the weight of the guncotton.

The whole of the acid is displaced in three hours, and the water, which should fill the pan, is run through the guncotton, the guncotton drained down and sent over to be boiled. These operations occupy about an hour.

The following are the principal advantages which the displacement process possesses over the Abel process, and over the direct dipping and nitrating centrifugal processes where they are similar to the Abel process.

1. The displacement process takes the place of the processes of dipping, squeezing out excess acid, digesting in pots, acid centrifuging, immersing, and water centrifuging.

2. The actual dipping of the cotton waste is a very much less laborious operation—the heavy labour of squeezing out the excess acid is done away with, the absence of fumes makes the work much healthier, and injuries to workmen from acid splashes are almost unknown.

3. Loss of guncotton due to decomposition in the digesting pots and acid centrifugals, and consequent inconvenience and danger to workmen from nitrous fumes, are done away with, and the heavy loss from breakages of pots and lids is saved. Three and a half years' experience has proved that the earthenware pans are very lasting.

4. Fumes during dipping, loading, and unloading acid centrifugals and immersing, are avoided.

5. The quantity of acid lost is very much reduced. This reduction means also very much less pollution of the escaping washing water.

6. The recovered waste acid is very much cleaner, a matter of the greatest importance from the point of view of revivification and concentration.

7. The mechanical loss of guncotton in the acid and water centrifuging processes, and in the immersing process, is saved.

8. A more thorough preliminary washing of the guncotton is obtained with an expenditure of about one-fifth

of the quantity of the water, and less boiling, with consequent consumption of steam, is required in order to reach a given standard of purity.

9. Great saving in power is gained by the abolition of the acid and water centrifugals, and in the reduction in the quantity of water which has to be pumped.

10. Renewals of plant, and repairs to plant and buildings are exceedingly low.

11. The number of hands employed for any given output is much less—the total cost of labour being reduced by two-thirds.

12. The yield is improved; it averages 170 per cent.

13. Finally, a more stable guncotton, of more uniform composition, is produced. It is also far cleaner, and contains notably less mineral matter.

STABILISATION.

Boiling.—Originally stabilisation was effected by prolonged washing in cold running water followed by a very short treatment with a boiling alkaline solution. Boiling, as now understood, did not form part of the process of guncotton manufacture when manufacture was started at Waltham Abbey early in 1872. About the middle of 1873, however, boiling vats were put up at Waltham Abbey, but no records exist, unfortunately, about the details of the early boiling processes. In the official "Notes on Gunpowder and Guncotton," published by the War Office in 1878, it is stated that guncotton manufactured at Waltham Abbey underwent two boilings by steam in wooden vats for 8 hours each, the water being extracted after each boiling by wringing for 3 minutes in clean water centrifugal machines. The same boiling process was in use in 1888, according to a later edition of the same book. Five years later each boiling was extended to 12 hours, and the boiling lasted for 5 days and nights—that is, the guncotton received 10 boilings of 12 hours each. In April, 1894, this system of boiling was replaced by a system characterised by short boilings at the commencement of the process, the time of successive boilings being gradually increased. The scheme of boiling was as follows:—

No. of boiling.	Duration in hours.	No. of boiling.	Duration in hours.
1	2	7	6
2	2	8	6
3	4	9	9
4	4	10	9
5	6	11	12
6	6	12	12

This system of boiling was continued with but slight modifications until August, 1905. On the introduction of the displacement dipping process it was found, as already stated, that guncotton made in this way was brought to a condition of stability by the boiling process then in use, and just referred to, at an earlier stage than guncotton made by the Abel process. A probable explanation of this fact is that during the displacement process a zone of acid liquid at a comparatively high temperature—somewhere about 40° C.—passes through the whole of the guncotton in the dipping pan. The action of this hot acid liquid may be to oxidise certain organic impurities which are certainly present, and to cause the breaking-down of unstable nitrogen compounds into soluble or non-reactive bodies. Systematic experiments were therefore carried out, in 1905, to determine the most suitable and most economical method of purification by boiling, for displacement process guncotton. In the principal experiments two types of boiling were employed—one in which long boilings were used at first, followed by short boilings; the other in which short boilings were used at first, followed by long boilings. The following deductions were made from the results obtained in these experiments:—

1. Purification of guncotton obtained by means of long boilings at the beginning followed by shorter boilings later, is superior to that obtained when the reverse condition holds. This is substantiated by the following considerations:—Examination of the waters showed that

neutrality is obtained earlier; that less decomposition of the guncotton takes place; that the stability, as shown by the various stability tests, is greater; and that a stable condition is attained earlier.

2. A displacement washing after a long acid boiling at an early stage is a beneficial treatment. This treatment is probably responsible for the early attainment of neutrality.

The system of boiling determined on as a result of these experiments was as follows:—

No. of boiling.	Duration in hours.	No. of boiling.	Duration in hours.
1	12	6	4
2	12	7	4
3	4	8	2
4	4	9	2
5	4	10	2

with a cold water displacement wash after the first two boilings. A full account of these investigations was given in a paper on the purification and stabilisation of guncotton, read by Dr. Robertson before this Section on June 16th, 1906. This system of boiling is still in use at the Royal Gunpowder Factory.

The question of how the purification of guncotton can best be effected cannot, however, be considered as settled, nor can the system which has just been described, although it undoubtedly gives an excellent guncotton at the Royal Gunpowder Factory, be applied to guncotton made by other processes, at other factories, without full investigations as to its suitability. Another matter which must be taken into account in connection with the purification of guncotton by boiling, is the nature of the water available. The water at Waltham Abbey is very hard, and its alkalinity may be an important factor in the success of the boiling treatment in use there. This question is perhaps connected with another one, and that is, that the boiling of guncotton can be carried too far. The effect of boiling, whilst it no doubt breaks down impurities, also, no doubt, breaks down the stable ester itself. It is well known that if guncotton is boiled for a sufficiently prolonged period, the percentage of soluble matter will rise and the nitrogen-content will fall. The breaking-down of the ester will be accompanied by the formation of acid bodies, and the presence of alkali in the water will neutralise them and prevent them from reacting on the guncotton.

I have been obliged, owing to want of time, to treat this question of purification very briefly, but it is undoubtedly the most important one in connection with the manufacture of guncotton. One or two matters have been touched upon, in connection with which further work is necessary, but there are many others which will repay very careful investigation and research.

PULPING.

On completion of the boiling process the guncotton is transferred to a heating engine somewhat similar to that employed for pulping the raw material used in the manufacture of paper. It consists essentially of a large iron roller armed with steel knives, and a bed-plate also provided with knives. The roller revolves, and as the guncotton passes between the two sets of knives, it is reduced to pulp of any desired fineness. As the pulping process proceeds, the roller is gradually lowered nearer to the bed-plate.

Since the introduction of a thorough system of purification by boiling, Abel's original idea that the pulping and washing the guncotton received in the pulping process had a very material effect on its purification, no longer holds good to the same extent. At the same time there is no doubt that the very long staple guncotton before pulping retains in its tubes unstable bodies which no reasonable amount of boiling will remove. The effect of pulping is to materially reduce the length of the fibres and, at the same time, to produce a certain amount of crushing in them. This allows of impurities of an acid character in the tubes being removed, either mechanically or by diffusion.

GUNCOTTON DISPLACEMENT—NITRATION MACHINE.

GUNCOTTON BEATERS AND POACHERS.

COTTON WASTE TEASING MACHINE.

GUNCOTTON ROLLING HOUSE.

REMOVAL OF FOREIGN BODIES.

After pulping, it is now customary to treat the guncotton in some mechanical way, in order to remove from it particles of metal, grit, and foreign bodies of a similar character. At the Royal Gunpowder Factory this is effected by running the guncotton pulp, suspended in a large volume of water, through grit traps, placed at intervals in a long shallow trough, the bottom of which is covered with blanket. The foreign bodies, being almost entirely heavier than the guncotton pulp, are retained in the grit traps, and the fine sand, also present in some quantity, is caught by the woolly blanket. An electro-magnet in the last grit trap removes any magnetic particles passing the ordinary grit traps. It is surprising what a large quantity of foreign bodies are removed by these arrangements. In addition to grit traps and troughs, some factories use what is known as a knotter, the function of which is to remove small knots and any large pieces of guncotton which may have escaped complete pulping.

POACHING.

Washing the guncotton during the pulping is effected in some factories by the use of drum washers fixed to the beating engine; in other factories and at the Royal Gunpowder Factory this washing is done in separate vessels, termed "poachers." The poachers in use at Waltham Abbey hold about 10 cwt. of guncotton and 1100 gallons of water, and are fitted with power-driven paddles for agitation purposes. The guncotton receives at least three washings; it is allowed to settle down after each washing, and the washing water is removed by a skimmer. The washing water contains in suspension foreign bodies of a lower specific gravity than guncotton, and in the case of the earlier washing waters, there is always present a scum containing nitro-bodies of low stability.

BLENDING.

A further purpose served by poaching is the thorough blending of a number of different batches. This is a final blending, but at the Royal Gunpowder Factory there exists a regular system of blending right through the whole of the manufacturing processes. This system is briefly as follows:—The cotton waste reaches the factory in consignments from different contractors. The waste is drawn from store in proportion to the quantities on the contracts, and is mixed and passed through the teasing machine in these proportions.

The next process where blending is possible is in charging the boiling vats. Two vats are filled simultaneously from a number of sets of pans—two pans of each set of four going into one vat; the other two of the set into the other vat. On completion of the boiling, four vats are emptied simultaneously into 32 beaters. This ensures the guncotton from the four vats being blended together in the beating process.

On completion of the pulping the beaters are run alternately into the poachers in such a manner that the contents of the 32 beaters are blended into eight poachers. The guncotton in the eight poachers is therefore uniform throughout.

The system produces guncotton of very uniform nitrogen-content. In the 1907-8, 291 tests, representing 600 tons of guncotton, gave the following nitrogen result:—

Maximum.	Minimum.	Mean.
per cent. 13.05	per cent. 12.93	per cent. 13.0195

MOULDING.

For convenience in drying the pulped guncotton it is moulded by light hydraulic pressure into cylinders which measure about 5½ inches in height and 3 inches in diameter. This is effected by running the guncotton pulp into a moulding machine provided with a number of holes into each of which fits a hollow plunger. These plungers are connected with a vacuum engine, and a good deal of the water is sucked out of the pulp by their means. The

mould block containing the guncotton is transferred to an hydraulic press, and pressure is applied, which has the effect of removing more water and of squeezing the pulp into a condition of sufficient consistency to allow of its being handled with care. In this lightly compressed form a very much larger quantity of guncotton can be dealt with in a drying chamber of any given dimensions than if it is dried in the condition of ordinary pulp, and in its compressed form it possesses the further advantage of being able to be dried on fixed racks. This does away with the necessity and risk of moving drying trays or similar arrangements in a stove. It is also obvious that much less dust is produced.

PRESSING.

If intended for use in torpedoes, mines, or other demolition work, the guncotton is moulded into suitable shapes, as described above, and the moulds are then subjected to powerful hydraulic pressure, amounting to about 6 tons on the inch, to produce the finished slabs or primers.

CONCLUSION.

I have endeavoured, very imperfectly I am afraid, to give in a comparatively brief time some account of the history of the manufacturing processes involved in the production of guncotton. Other nitrocelluloses, for the manufacture of which some of the processes are slightly modified, have not been touched upon. The subject is a very wide one, and if it were attempted to go into details, each process would require more time devoted to it than has been given to the whole manufacture.

This paper has consisted almost entirely of manufacturing details; very little attempt has been made to deal with the chemical questions involved, and nothing at all has been said about the chemistry of the nitration of cellulose nor of the chemistry of the nitrocellulose molecule. The published information on both these subjects is very considerable, and is constantly increasing. I had originally intended to attempt a brief summary of the more important papers, but I had to abandon it as quite impracticable. What must, however, strike any manufacturer of nitrocellulose when he consults the literature of the subject, is that the great bulk of it, although of intense interest, is either too theoretical for practical application, or else that the data, being for the most part the result of laboratory experiments, are not always a sure guide as to what will happen on a manufacturing scale. Our experience at the Royal Gunpowder Factory is, and it is also no doubt the experience of other manufacturers, that all experimental work should be based on sound chemical principles, but to be of practical use it must be conducted on a manufacturing scale wherever possible, and that laboratory work comes in when it is required to ascertain the nature of the results obtained. I venture to think that this is true in the case of several chemical manufactures, and it is most undoubtedly true in the manufacture of guncotton, and I therefore offer the suggestion to any of those chemists who wish to further improvements in the production of guncotton, to take the manufacturer into their confidence, work with him, and to get him to work with them.

DISCUSSION.

The CHAIRMAN asked whether there was any difference in the behaviour of cotton fibres of different origin, such as Bombay, Egyptian, and Sea Island fibres; of course, they might all be too expensive. There were some other fibres which might perhaps be used, such as the Kapok fibre and the fibre of *Cochlospermum Gossypium*, which the "Indian Museum" in Calcutta was examining at present. Those who had been allowed to see Waltham Abbey in 1900 would realise the vast advances that had been made since then, judging from the pictures thrown on the screen. He could not fully agree with what had been said about the functions of a works laboratory. In the presence of so many military men, it was rather obvious to draw the parallel between strategy and tactics in military matters and in a chemical works. The laboratory could be likened to the General

Staff which laid down the plan of campaign. And just like the tactician had to work it out in the field, so in the same way the chemist who had made the experiments on a small scale, had his work cut out for him when endeavouring to carry them out in the factory on a larger scale. No doubt the chemist would meet then with many seemingly insuperable difficulties; but having once got the result in the laboratory, he knew he had only details to deal with, however long and patient the work involved in overcoming them might be. At the same time the laboratory must supervise the large scale operations from the beginning, and in all its stages, and not simply come in at the end. Sir Frederic Nathan was in the enviable position of being able to show what he was doing, whilst manufacturers as a rule had to be more reticent; this paper, therefore, was especially instructive to the younger members of the Society, who learnt the supreme importance of details, and what amount of foresight was required to carry on a manufacture successfully. The thanks of the members were also due to the Government, who permitted the publication of all the details.

Mr. JOHN SPILLER said he had listened with great pleasure to this history of things as they were, in bygone years, when he was one of Sir F. Abel's assistants; and also to the interesting narrative of successive improvements introduced into the manufacture. He noticed particularly the considerable saving of labour, the larger production, and especially the greater purity of the finished product. It must afford every chemist the greatest satisfaction to find that matters were brought up apparently to the ultimate stage of perfection. He was in Abel's laboratory in the early days of guncotton, even before it was manufactured at Waltham Abbey or only made on quite a small scale; and he was there later when the disastrous Stowmarket explosion occurred. A year or two afterwards he was Mr. E. O. Brown's colleague when he cleared up the mystery, and gave the first indication of the true cause of that disaster, which he did by proving that even moist guncotton could be fired by detonation. There were many narrow escapes in those early days. Brown himself only escaped with his life on one occasion by a few minutes, when he came away from inspecting the magazine at Plumstead Marshes, and told them he had hardly time to lock up the place and run away. He was intending to report to Prof. Abel, but had no time to do so, because the whole thing exploded, in consequence, as it was proved, of the escape of red fumes due to decomposition. He assisted in the working out of the boiling process and some of the other operations which had been referred to. He lost the hair off one side of his face through a premature explosion in testing guncotton by heating it in a flask so as to determine the temperature at which the red fumes made their appearance. At the time they did not know everything about guncotton, and it was probably not so well purified as now. At any rate two men, a corporal and a foreman of the Royal Laboratory, were killed on 24th May, 1875, by an explosion which occurred during the compression of the blocks.

Colonel Sir HILARIO BARLOW said he was probably the largest user of guncotton in England, as they filled at the Royal Laboratory all the mines and torpedoes. Wet guncotton was a very innocent thing if it were pure, and there was not much to be apprehended from handling it, but the great difficulty was to arrange to keep it wet. Owing to the circular section of torpedoes it was necessary to shape the oblong slabs of guncotton used for filling in order to fit them in, and the slabs had to be cut up with hand saws, and of course there was a great deal of fluff or moist dust produced, and it was not an easy matter to keep the floors on to which this dust fell from getting dry. They endeavoured to keep them constantly moist, but everybody knew what workmen were, and how difficult it was to make them look after themselves. Amongst other things they tried a floor sloping from the centre to the sides with a perforated water pipe running down the middle, so as to get the flow in each direction, but it did not answer, because such an enormous flow of water from one pipe was necessary to keep a large

building wet all over, while a multiplication of pipes made many undesirable excrescences on the floor. Ultimately they had to revert to the humble watering can, which was very excellent if the men would use it. With regard to filling mines and torpedoes, there was always a hankering after using enormous blocks of guncotton, which looked at first sight an admirable system, but it was not as good as it looked. He made no criticism on the methods employed by one company he knew of who made the most admirable solid guncotton he had ever seen, so solid that a block of it over 400 lbs. in weight had to be put on the floor and cut with a cross-cut saw like a tree, in order to get blocks of it cut up for certain tests of the distribution of moisture. It was in connection with the distribution of moisture in wet guncotton that these large blocks were so inconvenient. With explosives nothing could be taken for granted; you had to find what the moisture really was, and therefore if a large block were being tested as a complete charge a piece had to be taken from the inside as one would from a cheese, and they had to invent a tool for taking these tests. It was a difficult problem, because one could not allow the water to run on the tool, as it would at once destroy the moisture test; therefore they had to have a tool with a water casing round it, and to bore in to a depth of something like 14 inches to take out the sample column and test the moisture therein. Further as to repairs. When the torpedoes were filled with a few large specially shaped blocks, the blocks retained as spare for the carrying out of repairs were only of use for the one purpose, whereas if the charges were built up of slabs like bricks of about 2 lbs. weight each, and such slabs were used for all purposes, the keeping of spare slabs for repair purposes was a simple matter. At the same time, better density was obviously obtained by filling with a few blocks rather than with a lot of small bricks.

Mr. WALTER F. REID said the author rather excused himself for not referring to the chemistry of the nitration of cellulose, but in his opinion those with most experience of the subject attached least importance to the many different views put forward on nitration, and the products derived from the operation. He thought also there was some little misunderstanding with regard to his concluding remarks about the position of the chemist. There was really very little difference between the analytical operations in the laboratory and the operations carried out in such a factory. The author had very fully utilised the services of the chemists at his disposal, being himself an excellent chemist, and when he listened to the method by which these acids were first mixed in bulk, then analysed, and then again brought up to the right strength, it occurred to him that many who for years had simply been mixing their acid by volume according to analysis had not sufficiently utilised the services of the chemist. Research work, on which the importance of all factory operations so intimately depended, had not been omitted; as was clear not only from the elaboration of this method of nitrating cotton, but also from the method of making nitroglycerin, which was described in a recent paper. The mechanical preparation of cotton still appeared to him to be somewhat crude. He would not say that this was not the best method at present on a large scale; but there still seemed something wanting in the way of a fine subdivision of the material both before and after it came in contact with the acid. He thought there was an opening also for an improvement of the process of weighing. The English climate was not always dry; there were times, as had recently happened, when the atmosphere was fully saturated with moisture, and unless special precautions were taken in exposing this finely divided, very dry cotton, it would absorb a considerable and variable quantity of moisture. This was a very difficult problem, and still awaited solution. With regard to the yield obtained, and the very large output per man in the factory, in spite of all displacement of labour, he thought labour of that kind ought to be displaced wherever it could, because the men worked under great sanitary disadvantages, and if they could in any way supplant human labour of this kind by appliances it was good for humanity. With regard to the materials used, he did

not think they had by any means reached finality, and there might be many possibilities ahead. Curiously enough, the material used was most unsuitable from its mechanical shape: the cotton fibre was a capillary tube, and unless that tube was absolutely destroyed, one could not prevent the strong capillary action with which it would retain all liquids. Until the structure was destroyed one could not be absolutely sure that the guncotton was perfectly pure. He had tried some small experiments in that direction: instead of the machine adapted from the paper industry, he had tried fine grinding, and it was quite possible on a large scale to absolutely reduce the fibres to a powder. Then the subsequent purification would be simpler, and probably the cost would be reduced. Many years ago he had tried a number of fibres which were not tubular, one of which, kapok, had been already mentioned. He thought Sir Frederic Nathan found it was a very greasy material, and he did not get a good yield from it. Incidentally, the sample of kapok, of which he had obtained a considerable quantity, had been finally utilised for another purpose. It repelled water so effectually that it had been used as a material for lining the inside of the cars of the balloons that took part in the long distance race for the Gordon-Bennett Cup. It had since been used by balloonists for lifebelts. In one explosive industry, at any rate, that of Schultze powder, one of the first smokeless powders made for sporting purposes, the cellulose from wood had been used. It was quite possible that with higher purification of wood fibre and reducing it more to the terms of cellulose, it might ultimately become a substitute for cotton in this industry. It must be remembered that they were in rather an awkward position in the explosives industry being dependent both for nitric acid and cotton on other countries; so that if the supply of either or both should be cut off they would not be able to make cordite or the other nitrated material. It would therefore be an advantage if they could find some substitute for cotton, which could be used for making nitrocellulose.

Mr. OSCAR GUTTMANN said the figures by the Abel process were given as 13.75 to 1.25 of cotton waste or 1 in 10, which was the quantity remaining in the pots after dipping and squeezing out the acid on the grid at the back, but the nitration took place in 220 parts of acid. The nitration lasted 5 minutes, but the after nitration in the pots 24 hours. The nitration was probably finished as to over 90 per cent. within the first 5 minutes, and only the last 10 per cent. were finished in the next 24 hours by the acid absorbed by the cotton. The reason so large a quantity was required was that the cotton itself was so absorbent that it could not be dipped unless there had a large excess. There were also some figures raising with respect to the output per man in the nitrating centrifugal machines; he believed it was about the same as by the Ardeer process. While it was quite true that the output per man was very much larger in the case of the displacement process, they ought to consider that by the nitrating centrifugal at least six operations can be made in a day, whilst according to the description given in the *Zeitschrift für das gesammte Schiess- und Sprengstoffwesen* in 1905, which was still true, it took at Waltham Abbey 7 to 8 hours to finish a charge. Still, this was only a feeble criticism on what was otherwise an excellent process, carried out in the absence of fumes and inconvenience to the workmen, and giving excellent guncotton such as required at Waltham Abbey. They had, however, heard from the author that it probably would not be quite as useful for other kinds of guncotton: at any rate, it would have to be tried, and he thought these trials were wanting. He could not be expected to go fully into this process, nor into the whole question of the manufacture of guncotton, since about a month ago he had done this in another place. Mr. Reid suggested that wood fibres when better purified might be useful for the production of explosives, but trials had shown that, for the reasons Mr. Reid had given, they could not get the same good result from it as from cotton. He asked the author to what he attributed the yield of 170 as against 159 and 160 of other processes. They knew that he was not a friend of the nitrating centrifugal

machine, but he saw no reason from a mechanical and manufacturing point of view why the yield should be 6 per cent. better in one case than in the other. His impression was, that at Waltham Abbey they took much greater care in selecting and preparing the materials and in the manufacture, and that this was entirely responsible for the increase. Finally, as one who had seen more than half the guncotton factories in Europe, he would say that small laboratory experiments with explosives were not directly transferable to the factory, and that in this sense Sir Frederic was quite right. He was however the last man to deprecate the work of the laboratory, because it always showed the way, and two of the most brilliant examples were the investigations of Professors Lunge and Will, who by their work had suggested a very large number of improvements. A laboratory experiment might be made on 5 grms. or on 5 lb.; and manufacturers nowadays make the latter, because experiments on large charges were absolutely and directly transferable to manufacture.

Sir FREDERIC NATHAN said the question raised by the Chairman with regard to laboratory and manufacturing experiments had been very ably answered by Mr. Guttman. He had stated in his paper that all experimental work should be based on sound chemical principles; that implied that the laboratory initiated experiments, but that the experiments themselves must be conducted on the manufacturing scale. In writing as he had done, he had in his mind an immense amount of very valuable literature on the subject of guncotton, but it had been his experience that following the method described, resulted in failure to produce on the manufacturing scale anything like the bodies obtained by those very able chemists who had worked on the laboratory scale. As regards cotton waste substitutes he had tried unsuccessfully a large number of other materials besides those he had mentioned. By the time the percentage of resistant cellulose, suitable for nitration, had been got, a vast amount of time, labour, and material had been expended for a very small result. With regard to the "teasing" system, he had described it simply as it existed; other methods had been tried, e.g., reducing the cotton waste to the condition of cotton wool, but there was nothing at all gained; on the contrary, considerable extra expense was incurred with no corresponding advantage. The method of weighing the cotton waste appeared perhaps rather crude, but when dealing with very large quantities, and a difference of $\frac{1}{2}$ per cent. of moisture one way or the other was not a very serious matter, it affected the percentage of soluble mainly, in view of the fact that in the later guncotton processes there was a considerable blending, which was moreover carried right through the operations of converting the guncotton into cordite. He entirely agreed with the views expressed by Mr. Reid with regard to the purification of nitrocellulose; it was no doubt the one operation in the manufacture which they knew less about than they would like to. Experiments on this point are being constantly made with the hope that it would not only be possible to shorten the boiling process but at the same time be able to produce a much better guncotton than was being produced even at the present time. He agreed with Mr. Reid that destroying the fibrous structure of guncotton prior to purification and boiling would probably be a material step in advance. It had occurred to him and to others, and he believed a patent had recently been taken out for that purpose. With regard to the low yield from the nitrating centrifugal, he was unable to afford any explanation. Some of the reasons why a better yield was obtained with the displacement process was that there was no loss due to fuming off, either in pots or centrifugals, or in the mechanical operations of immersing, water-centrifugally, acid-centrifugally, etc., but mainly that a more complete conversion of the cellulose into nitrocellulose took place in this process.

Manchester Section.

Meeting held at Manchester on Friday, January 8th, 1909.

MR. R. H. CLAXTON IN THE CHAIR.

THE RELATION BETWEEN THE ABSORPTION OF MOISTURE AND OF DYESTUFFS BY TEXTILE FIBRES.

BY SYDNEY H. HIGGINS, M.Sc.

While engaged in an investigation dealing with the dyeing and bleaching of textile fibres and with the mercerising of the cotton fibre, certain observations were made which pointed to a connection between the amount of dyestuff the textile fibres were capable of absorbing from solution and the amount of moisture which those fibres attract from the air; the affinity for dyestuffs seemed to correspond directly to the moisture contents. It therefore seemed of interest to determine the amounts of moisture in different fibres under ordinary atmospheric conditions, and to compare the results obtained with the quantities of dyestuffs which these fibres are capable of absorbing from solution. In addition to textile fibres, inorganic absorbents, *e.g.*, China clay, were used. No conclusions, however, could be drawn from the figures obtained when solutions of Night Blue, magenta, Diamino Sky Blue and iodine were employed. Whilst, for instance, China clay which contained 0.68 per cent. of moisture absorbed 1.69 per cent. of Night Blue a sample of silica containing 13.56 per cent. of moisture only absorbed one-seventeenth part of the dyestuff taken up by the China clay. Cotton containing 5.85 per cent. of moisture absorbed 0.36 per cent. of Night Blue, whilst 8.82 per cent. of moisture and 2.36 per cent. of Night Blue were absorbed by silk. It was found that similar divergencies prevailed in all the other cases. Therefore it was decided that, considering how the absorptions of dyestuffs and of moisture by textile fibres are influenced by the conditions under which the absorptions are conducted, proper conclusions could only be drawn when the conditions of absorption were identical in all the experiments; so that as far as possible, the same absorbing material in different physical forms was used in each series of experiments.

Hübner having shown that iodine and dyestuffs are absorbed in a somewhat similar manner by textile fibres, solutions of iodine in potassium iodide were used in some cases. It was whilst engaged in the work mentioned that many of the results here recorded were obtained, and for this reason some of the figures given in the papers (Chem. Soc. Trans., 1907, 91 and 92, 1057—1073, and this J., 1907, 26, 105—112) will have to be quoted.

TABLE I.

Time of absorption in hours.	Grms. dyestuff absorbed by 100 grms. dry material.				
	Fibre length	3.12 m.m.	2.2 m.m.	0.7 m.m.	0.4 m.m.
	29 m.m.				
1	0.1525	0.1755	0.191	0.2295	0.245
6	0.188	0.191	0.2065	0.231	0.2605
18	0.2065	0.214	0.2215	0.235	0.2605
72	0.2065	0.2065	0.2605	0.2605	0.2605
	Grms. moisture absorbed by 100 grs. dry material.				
1	1.49	2.01	1.60	1.36	1.30
18	6.23	6.44	6.16	5.79	5.75
44	6.84	6.72	6.64	6.64	6.68
109	9.34	9.24	9.28	9.18	9.10
127	9.34	9.24	9.25	9.18	9.10

In Table I. the comparison between the rate of absorption of Night Blue by wool in various states of division and of moisture from the air by the dried out samples of wool will be seen. It will be noticed that after 72 hours

the amounts of dyestuff and moisture absorbed by all the samples is practically a constant. It is also shown that both the maximum absorptions of moisture and of dyestuff are obtained during 72 hours. Whilst the figures obtained for the absorption of dyestuff show a certain regularity, it will be noticed that this is not the case with the figures obtained for the absorption of moisture. This is, without doubt, due to the difficulty of conducting the moisture absorption experiments in such a manner that absorption takes place uniformly throughout the samples. It would be necessary to find a means of keeping the fibres uniformly in contact with the air.

Samples of cotton yarn were mercerised, with and without tension, and parts of these, together with a sample of the original yarn, were bleached. Weighed samples were then allowed to absorb iodine from potassium iodide solution, and at the same time their moisture contents were found after being exposed to the atmosphere for about a week. (Hübner, *loc. cit.*)

TABLE II.

Sample of cotton.	A Iodine absorbed by 100 grms. dry material.	B Moisture absorbed by 100 grms. dry material.	B A
Ordinary unbleached ...	0.3	6.52	21.73
" bleached ...	0.2496	6.25	21.59
Mercerised without tension unbleached	0.4622	9.33	20.19
Mercerised without tension bleached	0.4216	9.12	21.63
Mercerised with tension unbleached	0.4136	8.25	19.88
Mercerised with tension bleached	0.3556	8.05	22.63

Although there is a big variation in the figures in Columns 1 and 2, it will be noticed that those in the third column are practically constant. The absorption of iodine and of moisture by cotton is, therefore, of a similar character. The bleached yarn absorbs less iodine and also less moisture than the unbleached yarn in all cases.

In a further experiment cotton yarn was well boiled out and mercerised without tension with caustic soda of different concentrations. The samples were then washed, soured, washed, dried at about 60° C., and after this exposed to the air for a considerable time. The amounts of moisture were determined by weighing before and after drying for 8 hours at 100° C.

Moisture per cent.

Ordinary cotton	6.2
Mercerised with caustic soda 10° Tw.	6.37
" " " 20° Tw.	6.68
" " " 30° Tw.	8.40
" " " 40° Tw.	9.41
" " " 50° Tw.	9.43
" " " 60° Tw.	9.57
" " " 70° Tw.	9.69

These results if plotted along with the dye trial and shrinkage curves given by Hübner and Pope (this J., 1904, 23, 407), show a remarkable similarity between the dyeing and moisture curves, in that a big jump between 20° Tw. and 30° Tw. will be found, whilst the absorption is practically constant between 40° Tw. and 50° Tw., afterwards slightly increasing to 70° Tw.

Oxley (J. Soc. Dyers and Col., 1906) has stated that mercerised cotton does not dye to as full a shade after drying as when dyed after mercerising but before drying. It has been found that ordinary cotton behaves in a similar manner. It is also known that cotton cloth, which has been thoroughly dried, even after a long exposure to the atmosphere will not absorb the amount of moisture it originally contained in the air-dry state. I have conducted experiments on the large scale which fully bear out this statement. These observations go

further to prove that the drying of cotton hinders the absorption of dyestuff and of moisture.

It is interesting to note that the absorption of moisture by the cotton fibre is also influenced largely by the materials employed in the finishing processes. From Table III. it is seen that dextrin, unlike starch, has little effect in hindering the natural absorption of moisture by the cotton fibre.

TABLE III.

Sample of cotton.	Finishing material.	Moisture per cent. in unfinished piece.	Moisture per cent. in finished piece.
1	5.4% white dextrin	7.06	7.01
2	3.8%	7.13	7.2
3	3.0% soluble starch	8.0	6.2

The observations recorded above point to an analogy between the absorption by textile fibres of moisture from the air (*i.e.*, a vapour from a gaseous medium) and of dyestuffs from solution (*i.e.*, solids from a liquid medium).

DISCUSSION.

Mr. JULIUS HÜBNER said that he quite appreciated the difficulties mentioned with regard to the moisture absorption tests. It would be quite possible, nevertheless, to devise a method by means of which the cotton and the wool fibres could be disintegrated in such a manner that the mass could be kept uniformly in contact with the air during exposure. In quoting the remarks made by Mr. Oxley and by Dr. Knecht as to the absorption of colours by mercerised cotton which has been dried previous to the dyeing, he presumed that Mr. Higgins referred to similar experiments which the speaker carried out during September, 1907, and which fully bore out the observations made by Mr. Oxley. He had also observed, at the same time, that ordinary cotton behaved in a somewhat similar way; the difference in shade was, however, not as pronounced as when cotton treated with mercerising agents was used. The fact that ordinary cotton when dried after boiling and bleaching absorbed less colour than when it was dyed without previous drying had probably been observed by many dyers.

Mr. G. LAKE said that the author seemed to have exposed the cloth to the ordinary atmospheric moisture of the room. He himself had made many experiments on this subject, and did not agree with the statement that yarn or cloth would not take up their original amount of moisture again after being heated to 100° C.

Mr. WHITESIDE asked if the author had tried colour absorption experiments, comparing cotton pieces, which had been conditioned for some time, with pieces fresh from the loom. It was well known that it was difficult to obtain identical results in dyeing the two kinds of cloth.

Mr. CROWTHER asked Mr. Higgins what process he employed for the estimation of moisture in the fibres. He had conducted a series of experiments on the absorption of colour by mercerised cotton which he was sorry to say were never finished. He noticed, as Mr. Higgins had stated, that mercerised cotton lost moisture the longer it was allowed to remain in a dry atmosphere, and that this loss was proportionate, as far as he could tell, to the diminution in the affinity for colour. He was unable to obtain a point of equilibrium with regard to the substantive cotton colours. It appeared that the phenomena of mercerisation were in no sense permanent under ordinary atmospheric conditions.

Mr. ARDERN said that assuming the effect of mercerising as to increase the surface of the cotton, he would suggest that this might to some extent account for the increased finity for water.

Mr. HOSEASON said, that in the mercerisation of cotton, there was, apparently, a possibility of dissolving or changing minutely occurring colour selective bodies, resembling the staining of certain animal and vegetable

cells which, as was well known, absorbed some colours selectively. Had any experiments been conducted conclusively, say, with fibre freed as far as possible, by chemical means, of these possible selective substances?

Mr. HIGGINS, in reply, stated that if the heating of cotton to 100° C. had an effect on the affinity for dyestuffs then the heating to a lower temperature of say 80° or even less should have some effect. With regard to the surface of mercerised cotton, he was inclined to agree with Mr. Ardern, namely, that an increased surface was exposed. As to the effect of mercerisation dissolving out some constituents of the cotton, he considered that it was acknowledged that this was not the case. The gradual loss of moisture by mercerised cotton in the air was very interesting. The moisture determinations were made in each case by heating the cotton yarn for eight hours at 100°. In reply to Mr. Lake, he stated that the pieces were exposed for three weeks, and weighed repeatedly during that time. Though the moisture in the air during the three weeks would vary considerably, the pieces never came back to the original weight. He fully agreed with Mr. Hübner that it was desirable that the matter should be investigated more fully.

A VOLUMETRIC METHOD FOR THE ESTIMATION OF TITANIUM AND OF TITANIUM AND IRON IN THE PRESENCE OF EACH OTHER.

(A communication from the Chemical Department of the Municipal School of Technology, Manchester.)

BY EVA HIBBERT, A.M.S.T.

In the Journal of the American Chemical Society (1895, p. 878), Wells and Mitchell describe a process which is really an improved modification of Pisan's method for the estimation of titanium, and which depends upon the oxidation of a titanous salt by means of potassium permanganate. By this method both iron and titanium are estimated together, and it is necessary to apply special means to determine the iron; the titanium being found by difference. The process described by these authors involves the use of sulphuretted hydrogen for the reduction of the iron, and the method is rather a long one.

It was shown by Knecht and Hibbert (*Ber.*, 36, 1549) that by reducing a titanous salt with zinc and hydrochloric acid in a flask fitted with a Bunsen valve, the titanium could be estimated directly by titration with a standard solution of ferric iron, using potassium sulphocyanide as indicator.* In the same paper the authors also showed that it was possible to estimate iron in the ferric condition by means of titanous chloride, and the method, while giving accurate results, renders possible the volumetric estimation of ferric iron in a much shorter time than by the reduction of iron to the ferrous condition and subsequent oxidation with permanganate.

In the *Chemiker Zeit.*, 1907, p. 639, Prof. Knecht drew attention to an extremely delicate test for titanium, which was based on the reducing action of titanous chloride on methylene blue, and by means of which the metal could be detected in amounts even less than 0.00001 grm. The method, which is described below, is based on this observation. The titanium must be in the reduced condition, that is, in the form of a titanous salt. In order to secure this, the solution of the titanous salt is introduced along with some hydrochloric acid, into a flask fitted with a rubber stopper having three holes; one of these is fitted with a Bunsen valve, through which a platinum wire having a piece of zinc attached to it is passed, and the other two holes are temporarily closed with two glass rods (see sketch). In this way the zinc is suspended in the

* In a paper read before the Soc. chimica di Roma in Feb., 1907, G. Gallo takes credit for the use of the identical reaction for the volumetric estimation of titanium, but it is clear that the method was anticipated four years previously.

titanium solution, and when the reduction has proceeded for 15 to 20 minutes and the solution has been boiled, one of the glass rods, A, is removed, and a stream of carbon dioxide is passed into the flask, through a tube inserted in its place. The zinc is removed from the solution by raising the platinum wire through the small pierced indiarubber stopper at C, and the other glass rod, B, is then removed also. After the zinc has been washed with a little freshly boiled water, passed from a wash bottle, the solution is titrated with standard methylene blue run into the opening at B from a burette. The methylene blue is standardised by titration with titanous chloride.* The titanium in the titanium potassium fluoride used in 1903 was estimated in this way, the original method with iron alum was repeated, and the estimation was also done gravimetrically. The results were as follows:—

Titanium by methylene blue.	By iron.	Gravimetric.
(1) 18.54%	18.56	18.47
(2) 18.46%	—	—
(3) 18.38%	—	—

Theoretically titanium=18.60% for $K_2TiF_6 \cdot H_2O$.

To prove beyond doubt that the interaction between titanous chloride and methylene blue is quantitative, the recrystallised methylene blue zinc double salt was titrated with titanous chloride, and gave 100.15 per cent. This was used for titrating the recrystallised potassium titanium oxalate, $TiO.C_2O_4.K_2C_2O_4$, dried at $100^\circ C$. This gave 14.76 per cent. of titanium (theoretical, 15.07 per cent.).

In order to show that the method employed for dissolving the titanium in an ore is satisfactory, that process was used in the case of the double oxalate. It consists in fusing the substance with about 10 parts of caustic potash in a nickel dish. The melt is allowed to cool, and is then treated with water, transferred to a beaker, and hydrochloric acid is added.

Titanium and iron.—Ferrous chloride will not reduce methylene blue, so that the method affords a means of estimating titanium in the presence of iron. The mode of procedure is exactly the same as if titanium is present alone, and the iron can be estimated in the ferric condition in a separate portion by titration with a standard solution of titanous chloride. In order to prove the possibility of estimating titanium in the presence of iron, mixtures

of known quantities of iron and titanium were prepared, and the titanium was estimated by the methylene blue method. When much iron is present, it is necessary to allow the zinc to react for at least 20 minutes in order to ensure the complete reduction of both iron and titanium.

Experiment.	Titanium found, grm.	Titanium taken, grm.	Iron taken, grm.

The method is specially adapted for the estimation of titanium in minerals and steel. In using it for the latter purpose, however, it should be borne in mind that the salts of the lower oxides of vanadium and of tungsten also exercise a reducing action on methylene blue and on ferric salts.

ON THE VOLUMETRIC ESTIMATION OF COPPER AND CHROMIUM, AND OF COPPER, CHROMIUM, AND IRON IN ADMIXTURE.

BY EVA HIBBERT, A.M.S.T.

In a recent number of this Journal (1908, 673) S. B. Jatar describes a process for the volumetric estimation of iron and chromium in one solution. Since copper and chromium are frequently met with together in the ash of mordanted and dyed textile material, and in some cases even copper, chromium, and iron may be present, I have, at the suggestion of Prof. Knecht, worked out a process by means of which these three metals can be volumetrically determined in presence of each other. The estimations are based partly on Rhead's process of estimating copper, partly on Jatar's process for the estimation of chromium and iron, and partly on new data which I have obtained experimentally.

Copper and chromium.—For this estimation it is necessary to have the copper in the cupric condition, and the chromium as a salt of chromic acid. The amount of titanous chloride required to reduce both copper and chromium is first ascertained, and then alternative methods can be employed for determining one of the other constituents in a fresh portion of the solution.

The simplest way is to pass SO_2 through the solution, boil off the excess of sulphur dioxide, and titrate the copper with titanous chloride as described by Rhead (Journ. Chem. Soc., 1906, 1491). Another method, which is somewhat longer, is to estimate the chromium alone, by first removing the copper with sulphuretted hydrogen, and then oxidising the chromium to bichromate with hydrogen peroxide. The bichromate is estimated by titration with titanous chloride. In Jatar's paper two methods are given for the estimation of chromium. The indicator used in one of these methods consists of a mixture of ferrous sulphate and potassium sulphocyanide used on a spot plate, and in the other method (c), the indicator is practically ferric iron and potassium sulphocyanide in the solution of chromium titrated. I have found that when the latter method is used, *i.e.*, first titrating with excess of titanous chloride, and then estimating the excess of titanium with iron alum, using sulphocyanide as indicator, reliable results are obtained, and the process is more easily carried out than in using the spot plate reaction which is given the first place in his paper. This method was consequently adopted in working out the results detailed below.

Mixtures of known quantities of pure potassium bichromate and copper sulphate were prepared and titrated.

(1) Copper sulphate and potassium bichromate, titrated with excess of titanous chloride, and then titrated back with iron, using sulphocyanide as indicator, when the amount of titanium required corresponds to the copper and chromium present.

*Knecht. Soc. of Dyers and Colourists, 1905, p. 9.

(2) Titration of the copper with $TiCl_3$, after the reduction of the bichromate with sulphur dioxide.

(3) Removal of the copper by sulphuretted hydrogen, oxidation of the chromium to bichromate, and the estimation of the latter by titration with titanous chloride.

	grms. found.		grms. taken.
Potassium bichromate	0.04915 gr.	by	0.04907
Copper sulphate	0.19979 gr.	SO_2 process (2)	0.200
Potassium bichromate	0.02455	Do.	0.02453
Copper sulphate	0.09994		0.10000
Potassium bichromate	0.04906	by	0.04907
Copper sulphate	0.09965	method (3)	0.1000

If the copper and chromium are not present in the condition of cupric salt and bichromate, it is necessary to oxidise and dissolve them before titrating. In order to ascertain whether this was possible, a known amount of potassium bichromate was converted into chromium chloride by heating with strong hydrochloric acid, the chromium chloride was mixed with a known quantity of copper sulphate, and chromium and copper were then precipitated together by boiling with sodium carbonate. The mixture of hydrates of copper and chromium was filtered off, washed, dried, and heated to redness. The ash was then fused with bisulphate of potash and afterwards made up to a known volume. It was found impossible to oxidise the chromium with sodium peroxide in the presence of copper, so the method adopted was to first titrate the copper with titanous chloride in one part of the solution, and in another to remove the copper with sulphuretted hydrogen, oxidise the chromium in the filtrate with sodium peroxide, add ammonium chloride, boil, and then titrate the bichromate with titanous chloride.

A mixture of 0.2 grm. of copper sulphate and 0.04913 grm. of potassium bichromate was found in this way to contain 0.20048 grm. of copper sulphate, and 0.04880 grm. of potassium bichromate.

Copper, iron, and chromium.—To facilitate the estimation of copper, chromium, and iron in presence of each other it was found desirable to introduce new methods for the estimation of chromium and iron present together. The potassium bichromate and ferric iron are first titrated together, and the amount of titanous chloride required is afterwards used to reduce another portion of the mixture. Potassium chlorate and hydrochloric acid is then used to oxidise the iron present, which is then again titrated with titanous chloride. Another method of estimating chromium and iron together, which is also a rapid method, is to titrate both iron and chromium with titanous chloride, and then to titrate back the iron with permanganate in presence of sulphuric acid. The following estimations were carried out:—

Estimation.	By chlorate method.	By permanganate.	Actually present.
Iron	0.03413	0.03423	0.03409
Potassium bichromate	0.04911	0.04899	0.04907
Iron	0.01529	—	0.01536
Potassium bichromate	0.04928	—	0.04907
Iron	—	0.01234	0.01236
Potassium bichromate	—	0.027895	0.02789

It is obvious that in these estimations the titanous chloride used must be free from iron.

Estimation of copper, chromium, and iron.—By the following process it is possible to estimate the amount of copper, chromium, and iron in a mixture (containing potassium bichromate, copper sulphate, and ferric iron) by only three titrations:—

(1) The solution containing iron, chromium, and copper is titrated with titanous chloride until the colour of the bichromate is changed to green, when potassium sulphocyanide is added, and the titration continued until all the red colour of ferric sulphocyanide has disappeared. Sulphocyanide is not added at the beginning of the titration, because potassium bichromate acts upon ferric sulphocyanide with the formation of persulphocyanogen.

(2) A known volume of the mixture is treated with sulphuretted hydrogen, the precipitated copper is filtered

off, and the solution boiled to expel sulphuretted hydrogen. It is then treated with potassium chlorate and hydrochloric acid, and well boiled, water added, and again boiled two or three times, and it is afterwards cooled and titrated with titanous chloride, using potassium sulphocyanide as indicator.

(3) A known volume is treated with sulphur dioxide, the sulphur dioxide is boiled off and potassium chlorate and hydrochloric acid are added to the solution, which is then boiled, cooled, and titrated with titanous chloride.

The results of the three titrations give:—(1) Copper, chromium, and iron; (2) iron; (3) copper and iron.

Some of the results which have been obtained are given below.

Example 1.—1 c.c. of titanous chloride = 0.002066 grm. of iron = 0.001807 grm. of potassium bichromate = 0.009186 grm. of copper sulphate. The amounts of titanous chloride required in the titrations were:—

(1) 46.4 c.c. required by iron + copper + chromium.

(2) 8.3 c.c. required by iron.

(3) 19.2 c.c. required by iron + copper.

From these figures it will be seen that the copper present required 10.9 c.c., the chromium 27.2 c.c., and the iron 8.3 c.c. of titanous chloride.

Therefore the solution contained:—0.04915 grm. of potassium bichromate, 0.10015 grm. of copper sulphate, and 0.01715 grm. of iron. The amounts actually present were:—0.04907 grm. of bichromate; 0.1000 grm. of copper sulphate, and 0.01723 grm. of iron.

Other examples:—

	II.		III.	
	Found, grms.	Taken, grms.	Found, grms.	Taken, grms.
Potassium bichromate	0.04896	0.04907	0.02295	0.02304
Copper sulphate	0.1002	0.1000	0.07485	0.0750
Iron	0.04338	0.04318	0.03016	0.03015

Copper, chromium, and iron, in the form of the oxides, CuO , Cr_2O_3 , and Fe_2O_3 , were obtained in known quantities in admixture in the following way:—Potassium bichromate was treated with sulphur dioxide, the product was mixed with pure ferrous sulphate and copper sulphate, caustic soda was added to the boiling solution, and the precipitated hydrates were filtered off, washed, and dried. The dried precipitate was heated to redness, and the ash was then fused with potassium bisulphate. The melt was taken up with water, made up to a known volume, and portions were treated in the following way:—

(1) Titrated with titanous chloride, using sulphocyanide as indicator, to determine iron and copper.

(2) The copper was removed with sulphuretted hydrogen, and the iron, after oxidising with potassium chlorate, was determined in the filtrate by titanous chloride.

(3) The copper was removed with sulphuretted hydrogen, and the chromium and iron were oxidised with sodium peroxide, the excess of hydrogen peroxide was boiled off, hydrochloric acid was added, and the chromium and iron estimated.

The following results were obtained:—

	I.		II.	
	Found, grms.	Taken, grms.	Found, grms.	Taken, grms.
Potassium bichromate	0.04926	0.04913	0.04880	0.04913
Copper sulphate	0.39963	0.400	0.20048	0.2000
Iron	0.05232	0.05254	0.02632	0.02627

DISCUSSION.

Mr. H. L. TERRY said the volumetric estimation of copper by titanium salts was new to him. How did the titanium method compare in point of accuracy with the three processes in general use, *viz.*, the electrolytic, the iodide, and the cyanide methods? He meant more particularly with regard to ores and metallurgical products than on mixtures prepared in the laboratory. It was mentioned that in the analysis of iron, chromium, and

copper mixtures it was necessary to separate the copper, and that this was effected by sulphuretted hydrogen; it was much pleasanter to precipitate the copper with sodium thiosulphate. He always used this method in separating copper in the iodide or cyanide assay. With regard to the cyanide assay, which many chemists seemed to think could only yield approximate results, he might say that at some large copper mines in Norway it was the sole method employed for ores, mattes, and metal; at any rate this was the case on the occasion of his visit three or four years ago. If the assay was carried out on strictly defined lines it was capable of giving results of much greater accuracy than was generally supposed.

Mr. SHEPHERD said he had used the titanium method for the estimation of copper in the vats for the electroplating of iron rollers. There was often a fair amount of iron present, which it was not necessary to estimate; excess of ammonia was added to the amount taken, the ferric hydroxide filtered off and washed with dilute ammonia, the filtrate acidified, and the copper titrated in the usual way with titanous chloride.

Mr. S. B. JATON, referring to his paper published in the *Journal* of July 15th last, said that Miss Hibbert mentioned that the "c" method is preferable to the one described as "a" method; the method "a" was mentioned in connection with pure chromium salts, and not chromium and iron together. The indicator was very useful when titanous chloride was to be standardised against bichromate solutions. The "b" and "c" methods could only be used accurately when one was familiar with the delicate colour reactions involved, which required a certain amount of practice. The indicator, therefore, was a great help for one not familiar with the method.

Mr. HOSEASON asked if there was any objection to the use of hypochlorite instead of chlorate as an oxidising agent, since the former was more easy of manipulation.

Mr. LOMAX inquired if the method of estimation had been applied to the analysis of rutile.

Miss HIBBERT, in replying, said the reason why she had brought forward this method of estimating copper, chromium, and iron was, as explained in the paper, for the determination of these metals when they occur together in the ash of mordanted material. The use of hypochlorite for oxidising iron in the presence of chromium would appear to be very suitable, but she had used potassium chlorate and hydrochloric acid because they were more easily obtained in a high degree of purity. Estimations of titanium in rutile, ilmenite, and other minerals, by the methylene blue method, had been very successful. A sample of rutile, analysed by this method, was found to contain 91.0 per cent. of TiO_2 , and this agreed very closely with the iron method, but she had not yet confirmed the result gravimetrically. In reply to Mr. Shepherd, it seemed probable that when the iron was precipitated with ammonia, some copper was carried down also. Methods for the complete separation of these metals were suggested in the paper.

My subject involves the whole sampling process, whatever the nature of the commodity, substance, or conditions, and the making up of the ultimate sample for assay or analysis, regardless whether the material to be sampled is of such a nature that the separate portions drawn cannot be mixed, as for instance, wood pulp; or whether they can be mixed, as in the case of ores, coals, etc. R. W. Sindall, of London, has done considerable work on one important phase of this subject, namely, the determination of average errors. His methods consist in duplicate sampling and testing, and in this way checking the results or deducing the probable error and showing its commercial significance. So far as I know, this question under the title I have announced has never been dealt with. D. W. Brunton, in a paper, in Vol. 25 of the *Transactions of the American Institute of Mining Engineers*, entitled "The Theory and Practice of Ore Sampling," in reality enters into it when he says, "In proportion as a sample in preparation diminishes in weight by quartering, it must be re-crushed so that there shall be a constant ratio between the size of the sample and the largest particle." That is, the more nearly uniform or homogeneous any product or substance is, the smaller may be the quantity representing it. His problem is:—Given a quantity of ore composed of particles and pieces of irregular sizes, shapes, and composition, how must it be dealt with so as to arrive at a very small sample of a few grams, which shall represent in true proportion the mechanical condition and chemical composition of all the separate masses of the original pile? He says that the size of the sample in amount must always be in constant proportion with that of the largest particle. In other words—whatever the weight of the sample in preparation, the number of parts or particles must remain constant. In the practice of crushing and grinding there will always be a large proportion of particles smaller than the allowable largest, but this is incidental.

My subject deals largely with the probability and theory of errors. It is not my purpose to enter into all the mathematical refinements of this subject, even if I were able, since it is one dealing almost wholly with higher mathematics. I shall endeavour to pursue the subject only so far as it has a practical value for chemists and not for theoretical considerations.

I may divide the subject as follows:—1. A statement of the problem. 2. The law of errors. 3. The probability curve and the analysis of it. 4. A consideration of the mean value. 5. The relative accuracy obtained by drawing larger or smaller numbers of samples. 6. The determination of results within fixed limits. 7. The number of samples to be drawn.

The problem is not a determination of who is the best marksman from an examination of their shots at a target, neither is it a determination of what shots occupy a mean average distance from the bullseye. It is much simpler than a determination of this, the mean average distance from the bullseye of all the shots. This problem would involve a calculation in the area of the target, while the nature of ours limits the observation to points in a straight line, for instance, those lying on one diameter of the target. Nor is it the determination, which is true in a set of observations, as in determining the atomic weight of some element, or the estimation of the probable error from the truth in the mean of these observations.

Our proposition starts where the degree of truth in these ends, and is by nature susceptible of closer approximation. We assume that the mean of a large number of variations is the truth sought, and we want to discover how few of these observations we may select, the average of which shall not appreciably depart from the mean of the whole number. Let us suppose we have 500 separate packages of any commodity, as for instance, 500 rolls of sulphite pulp which have been run over a drying machine, generally a few points above and below the atmospherically dry limit, to determine the amount of moisture. If we draw a straight line and divide it into two equal parts we may represent the mean variation in moisture by a point at the centre, and from this point lay off in one direction distances representing the departures from the mean of each sample above, and in the other direction, lay off representative distances below the mean. Let

MR. F. E. ATTEAUX IN THE CHAIR.

A MATHEMATICAL VIEW OF SAMPLING, WITH REFERENCE TO THE DEGREE OF ACCURACY TO BE OBTAINED.

BY MARTIN L. GRIFFIN.

In a paper read before the New York Section of this Society, entitled, "Standard Methods of Sampling: A Review with some Suggestions,"* I referred to some ideas on sampling that I expected to give at an early date, but which have been delayed until this time.

* This *Journal*, 1905, 183.

us assume that we have tested these 500 rolls of pulp and find the results to be as follows:—

Positive departure.			Negative departure.		
Moisture between.	No. of rolls.	Per cent.	Moisture between.	No. of rolls.	Per cent.
4—5%	10	2	4—5%	10	2
3—4%	20	4	3—4%	20	4
2—3%	40	8	2—3%	40	8
1—2%	80	16	1—2%	80	16
0—1%	100	20	0—1%	100	20

Plotting as ordinates the number of rolls and the corresponding mean variation in moisture as abscissæ, we shall get the following curve:—

In doing so we shall observe: (a) That there are as many samples represented on one side of the origin as on the other. (b) That within equal distances from the origin on each side there is an equal number of samples represented. (c) That by far the greater number will arrange themselves very close to the origin. (d) That small errors are more frequent than large ones. (e) That the greater the variation the less the frequency, and hence very large variations do not occur.

Now any mathematical relation between a variation (X) and the probability of its occurrence (Y) must satisfy these characteristics. When such a function, $Y=f(x)$, is plotted as we have illustrated, it will have a maximum ordinate, OY, corresponding to the mean, that is, no error. It will be symmetrical with reference to this ordinate, the Y axis; and as X increases Y must decrease, until when X becomes very large, Y will become vanishingly small. This corresponds to the fifth observation above, namely, that very large variations from the mean cannot occur. As a matter of actual manufacturing operations they scarcely exist. For example, a manufacturer desires to dry his pulp so as to get the allowable limit of atmospheric moisture as nearly as possible. Obviously it will be his desire to do this, because he does not want to pay freight on water, or if he must he will use wet presses without any attempt to reach this degree of dryness. If any quantity falls below his standard they will be included in the average. If he were punctilious in his orders to his superintendent about uniform conditions of moisture it would mean that if any mishap occurred in drying, resulting in a very few very wet rolls, they would be thrown out, or if the workmen were careless and they were included it could not affect the result because the number (y) was so small.

$$Y = Ke^{-h^2x^2}$$

is the equation which represents this probability curve or curve of variation of any particular roll or average or any given number of rolls from the mean of the whole number. To find the meaning of the constant K, let us solve the equation by putting $X=0$, then $Y=K$, which is the maximum ordinate of the curve. K corresponds to the number of those rolls whose content in moisture coincides with the mean itself. The height at which the curve cuts the Y axis represents the magnitude of the arithmetical mean; K has nothing to do with the actual shape of the curve beyond increasing the length

of the maximum ordinate. It must be borne in mind that it is not the maximum ordinate for any value of X, and only coincides with it when $X=0$. It follows, then, that as K has nothing to do with the curve, the sampling of any of the K rolls has no influence in fixing the result and we may disregard them. Therefore, when $X=0$ and $Y=K$ the whole number of rolls are alike, i.e., any one of them represents the average. Hence the drawing of one sample only will suffice.

The meaning of h is found by making $K=1$ and plotting corresponding values of X and Y. For

$X = \pm \frac{1}{2}, \pm 1, \pm \frac{3}{2}, \pm 2, \dots$, when $h=1, \frac{1}{2}, \frac{1}{4}, \dots$ etc.

$$y = Ke^{-h^2x^2} \quad K=1.$$

In this way it will be observed that though all the curves cut the Y axis at the same point, the greater the value of h , the steeper will be the curve in the neighbourhood of the ordinate OY.

The physical significance of this is, that the greater the magnitude of h , the more accurate the results, and the less will be the magnitude of the deviation of individual samples from the arithmetical mean of the whole number. h relates to the number of rolls of pulp approaching in variation the mean; if it is very large, there is very little variation from the mean in the content of moisture; the condition of the rolls is practically the same, and hence very close to the mean average. In sampling the h rolls, where h is large, the possibility of error is greatly reduced, and when we know h is large the necessity for taking a fixed number of samples to keep within an allowable limit of error is much less. Mathematically h has been called "the absolute measure of precision."

At this point some observations regarding the expression "mean average" value should be made. We, as chemists, draw samples from irregular masses and piles of commodities, as coal, limestone, ores, or packages of different sizes and weights, and quite frequently they do not bear a fixed ratio to the mass or weight they represent, yet we grind or mix and average them arithmetically. In so doing we introduce a probable error by the manner of taking the samples. In order that the arithmetical mean may be free from all error, we must draw equal weights from equal quantities by weight. For instance, in the sampling of bales or bundles of wood pulp for moisture, if the determination is to be made from the aggregate weight of the separate samples, they should bear a constant ratio to the weight of the respective packages from which they have been drawn. Referring to our illustration of 500 rolls of moist pulp, we have proceeded on the assumption that each roll of pulp was of equal weight and that the sample represented the condition of the rolls, and that equal weight samples had been drawn. Under these conditions the arithmetical average of the samples would give correct results. In other words our samples might all be weighed together in one weighing. The general statement for this is:—The best value to represent a number of observations of equal weight is their arithmetical mean; while the best value of different weights is obtained by multiplying each observation by its weight and dividing the sum of the products by the sum of their different weights.

It has been demonstrated that the probable error of the arithmetical mean of a series of observations is

inversely as the square root of their number. From which we see how easy it is to over-estimate the effect of largely increasing the number of observations or samples. If E denotes the probable error of the mean of ten samples, in order to reduce this error one-half, or one-half E , we must draw forty samples, and to obtain one-third E we would have to draw ninety samples. The converse of this is that the probable error is increased directly as the square root of the number of observations is diminished, that is the reduction by one-fourth in the number of samples taken doubles the error.

I have made use of this illustration in which it appears that each roll of pulp has been tested, for the purpose of analysing the problem mathematically, and drawing the resulting conclusions. It is, of course, an ideal illustration, and the results of such a sampling and testing, if it were possible, would be free from error.

The fundamental preliminary to sampling a mass of any commodity which may be mixed and quartered down is that it shall be mixed and crushed and quartered down successively mechanically in the abstract, and that the weight of each successive quarter shall bear a direct relation to the size of the mesh of a corresponding screen, and that it shall all pass through this screen. A set of standard screens corresponding to a set of weights diminishing proportionally in the quartering process would be very valuable to chemists. In sampling commodities which cannot be mixed, the theoretical fundamental conception is that in the process by which they have been produced there is a certain cycle of varying conditions which repeat themselves. This is inevitably so. The cycle may be large and the frequency small, and if so the sampling must be extensive. If the cycle

is small and the frequency large the sampling may be trifling. But all of this is included in the main argument of this paper.

From the discussion of the subject thus far we see that the number of samples within certain limits to be drawn does not play as important a part as is generally supposed, however, its importance is greatly dependent upon the representative value of each sample. This, of course, pertains to the sampling. The sampler must be free from all bias and personal errors in his work, or there will be an added error. My paper, therefore, becomes an argument also for greater knowledge of the product to be sampled, how it has been produced, etc., and greater care and diligence in the mode of sampling. The commercial value of the products sampled will also play a very important part in determining what the allowable limit of error should be, and this will affect the number of samples and the mode of sampling.

We may therefore conclude that if a chemist is conversant with the history of the product which he is about to sample and knows how to draw proper samples, the number may be very limited, perhaps ten and not more than 20 or 25. If he lacks the knowledge and ability to do this part of the work, the drawing of almost any number of samples will not be trustworthy.

New York Section.

At a meeting of the Section on Nov. 20th, 1908, held at the Chemists' Club, Mr. Frederick Klein read a paper on "Selenium."

Journal and Patent Literature.

PATENT SPECIFICATIONS may be obtained by post by remitting as follows:—

English.—8s. each, to the Comptroller of the Patent Office, C. N. Dalton, Esq., Southampton Buildings, Chancery Lane, London, W.C.

United States.—1s. each, to the Secretary of the Society.

French.—1 fr. 25 c. each, to Belin et Cie., 56, Rue des Francs-Bourgeois, Paris (3e.).

German.—1 mark each (with full particulars) to Kaiserlich Patentamt, Berlin, Germany.

I.—PLANT, APPARATUS, AND MACHINERY.

PATENTS.

Separating subdivided solid matter from a liquid, particularly applicable for thickening ore pulp and for feeding or measuring the pulp or solid. E. E. and A. S. Elmore. London. Eng. Pat. 26,821, Dec. 4, 1907.

THE mud or pulp to be separated is fed into a conical vessel known as a "spitzkasten" and the separation takes place in the known manner. The invention relates to the provision of a chamber at the apex of the cone through which the separated solids are discharged. This chamber has an upper valve opening upwards and a lower valve opening downwards, and forms a kind of lock for the passage of the solids. The valves are operated alternately by concentric rods which pass up through the vessel and are actuated by mechanism situated on the cover. In order to sweep the solids into the apex of the cone, slowly rotating rakes are arranged within the tank, supported by a frame having wheels which run on a track situated, in order to avoid clogging by deposited solids, in the overflow gutter which extends round the upper edge of the tank.—W. H. C.

Evaporating or concentrating apparatus. J. and C. McNeil, Govan. Eng. Pat. 5069, March 6, 1908.

THE claim is for improvements in the apparatus described in Eng. Pat. 8763 of 1900 (this J. 1901, 160). The chamber or box forming the steam space has the top and bottom plates dished upwards parallel to each other. The upper plate is of greater diameter than the lower one,

so that the chamber has the shape of an inverted truncated cone. The tubes are set at right angles to the plates, and are consequently inclined to the vertical, but parallel to the side of the steam chamber. A circulating space is left between the chamber wall and the wall of the evaporator, and the liquid is introduced by a perforated ring fixed either centrally over the tube chamber or above the circulating space.—W. H. C.

Mixing and pulverising apparatus for liquids. A. Martin. Paris. Eng. Pat. 6552, March 21, 1908.

THE liquid to be pulverised is pumped by a set of three pumps driven from the same shaft by cranks set at an angle of 120° to one another, so that one pump is always working into a pressure chamber. From this chamber the liquid is allowed to escape under strong pressure controlled by a piston, actuated by a spring, into a system of narrow passages. The thin streams of liquid are broken up and mixed again in these passages and finally discharged from two opposite nozzles, whereby the liquid is atomised.

—W. H. C.

Recording the quantity of water or other liquid evaporated in a boiler or the like. J. Stratton and E. A. Claremont, Manchester. Eng. Pat. 10,588, May 15, 1908.

Two calibrated tanks, A, A', of equal capacity, and provided with an overflow, F, are fixed side by side at the same level. They are alternately filled with the liquid to be measured by the pipes, B, B', which are connected by a three-way tap, behind the tap, D, shown in the figure, to the supply main, G. They are alternately emptied by the pipes, C, C', connected by the three-way

tap, D, to the delivery pipe, H. The two taps are so coupled together that when one tank is being filled the other is being emptied, and *vice versa*. The delivery pipe, H, is connected by a branch, J, with a float tank, K, and the float, L, is connected by a rod, M, with the lever, N, and the quadrant, O, from which a rod, Q, depends and carries a pen, R, which records the movement of the float on the chart carried by the clockwork drum, S. The tank, A', being filled with liquid, the taps, D, are reversed, and A is filled and A' emptied. As soon as the taps are turned, the float-tank, K, is in connection with the tank, A', and the liquid rises in K, to the same level as in A'; the float also rises and an upward vertical line is drawn on the chart. As the level of liquid falls in A', it also falls in K, and the float falls also, the rate of fall being proportional to the rate at which liquid is withdrawn from A', and an inclined downward line is marked on the chart. When A' is empty, the taps, D, are reversed again and the process repeated. The quantity of liquid used is calculated from the record on the chart, S.—W. H. C.

Filtering apparatus. A. J. Arbuckle and A. Osborne, Johannesburg, Transvaal. Eng. Pat. 21,452, Oct. 10, 1908.

THE apparatus is similar to that described in Eng. Pat. 20,400 of 1908 (this J., 1909, 130), except that the filters consist of frames suspended from the periphery of a rotating frame. As the filters are lowered into the tank containing the pulp to be filtered, the suction valves are automatically opened, the clear liquid is drawn through and the solids left on the surface of the filter. The suction valves are closed shortly after the filters emerge from the pulp tank, and the deposits are drained by the suction. As the frame revolves, the suspended filters come in contact with a guide plate which tilts them at an angle, and at the same time the back pressure valve is opened and compressed air is admitted behind the filter surface, which causes the deposit to peel off and to fall on to a shoot. Another guide plate then engages with a roller at the end of the filter, and allows the latter to gently resume the horizontal position before re-entering the pulp tank.

—W. H. C.

Drying apparatus. J. E. Kohn, Bay City, and J. B. Roos, Owosso, Mich. U.S. Pat. 910,671, Jan. 19, 1909.

THE claim is for an inclined rotary drying cylinder mounted within a chamber provided with a fan to create a draught to remove the moisture-laden drying medium. The material to be dried is fed into the open upper end of the inclined cylinder and is discharged through openings near the lower end, which is closed by a tube-plate. From

the latter a number of tubes project longitudinally through the cylinder. The heating medium is caused to pass through the tubes and through the cylinder.—W. H. C.

Crystals; Manufacture of large ——. J. Bock, Radebeul, Germany. U.S. Pat. 910,490, Jan. 26, 1909.

SEE Fr. Pat. 374,968 of 1907; this J., 1907, 872.—T. F. B.

Digesters. T. J. Hutchinson, Fr. Pat. 394,208, Sept. 11, 1908. Under Int. Conv., Sept. 11, 1907.

Drying apparatus; Centrifugal ——. actuated by fluid pressure. J. W. and W. A. Macfarlane, Fr. Pat. 394,440, Sept. 4, 1908. Under Int. Conv., Sept. 10, 1907.

SEE Eng. Pat. 20,177 of 1907; this J., 1908, 1007.—T. F. B.

II.—FUEL, GAS, AND LIGHT.

Coals; Action of air and of oxidising agents on ——. O. Boudouard, Compt. rend., 1909, 148, 284—286.

THE author has examined seven samples of coal—anthracite, coking and smithy coals, and lignite. He finds that in all cases humic acid is produced on exposure to air, by slow oxidation of the coal. This action is much more rapid at 100° C. than at the ordinary temperature. The coking coals after this exposure, and formation of humic acid, entirely lost their coking power, and yielded a non-coherent residue on carbonisation. Humic acid is produced in much greater quantity by the action of nitric acid on the coal than by atmospheric oxidation. In this case there is sometimes increase of weight, sometimes decrease, according as the fixation of oxygen (and of nitrous residues) is greater or less than the evolution of carbon in the form of gaseous compounds. (See this J., 1908, 1197).—J. T. D.

Gases; Flameless combustion of ——. and conditions of incandescence lighting. J. Meunier, Compt. rend., 1909, 148, 292—294.

CONTINUING his researches (this J., 1908, 494), the author finds that a platinum spiral substituted for the usual mantle in a Welsbach burner can be kept incandescent by combustion of the gaseous mixture on its surface, without communicating flame; and that the incandescence is more vivid as the mixture is made to approach more closely, by opening the air-holes, the composition for maximum explosiveness. Moreover, the sensitiveness of the flame to outside influence is very great. A sudden pinch of the gas supply tube is accompanied by explosion; and if, before the visible incandescence of the wire has disappeared, the tube be suddenly released, there is again explosion and the flame is established, whilst if the release be gradual, the wire again glows without flame. Slight currents of air, produced by a wave of the hand or of a handkerchief at some distance, are enough to produce explosion and establishment of flame; and the sensitiveness of the burner in this respect is greater as the mixture is nearer the composition for maximum explosiveness.—J. T. D.

Measuring the air- or gas-supply to engines and furnaces. A. G. Ashcroft, Proc. Inst. Civil Eng., 1907—1908, 173, [iii].

THE experiments were undertaken to determine if the volume of air passing through an orifice could be accurately deduced from the difference of pressure existing on the opposite sides of the orifice. An oil-engine was converted into an air-pump, by setting the valves so that at every other stroke a charge of air was drawn in at the air-supply pipe and expelled through the exhaust. The volume swept through by the piston was calculated from an indicator diagram taken with a specially constructed, delicate indicator. This was found to differ for different speeds. The volume of air drawn into the pump per minute was found by multiplying the volume swept through at each stroke at the given

speed by half the number of strokes per minute. By this means it was possible to accurately determine the volume of air drawn into the pump when working at different speeds. The air-inlet pipe of the pump was connected to the pressure measuring apparatus and the latter was calibrated. It could then be used to measure the volume of air drawn into the air- or gas-engine, or furnace. The air-measuring apparatus consisted of a box, 5 ft. long, 1 ft. 9 in. wide, and 11 in. deep, shown in Fig. 1. It was connected at A, to the inlet-pipe of the pump and was provided at B, with a plate having a sharp-edged orifice, 3 in. diam. The bottom of the box consisted for more than half its length of india-rubber sheet in order to equalise the pressure inside. The pressure within the box was measured by a special pressure gauge, shown at C, Fig. 1, and on an enlarged scale in Fig. 2. A circular box, *a*, was connected to the interior of the measuring box by the pipe and tap, *p*, and with the air by the tap, *o*. A rubber diaphragm, *b*, 5 in. diam., was stretched over the box and strengthened by the disc, *e*. A long lever, *m*, was supported from the cross-bar, *d*, by a piece of thin steel spring, *c*, which acted as a fulcrum. A scale-pan, *K*, was attached to one end of the lever, the other end of which terminated in a pointer which indicated the position on the scale, *h*. The diaphragm, *b*, was connected to the lever as shown by a piece of thin steel spring, *f*, attached to *e*. In order to determine the pressure in the measuring-box, the tap, *p*, was shut and *o* was opened. The position of the pointer on the scale, *h*, was noted and the tap, *o*, closed. The tap, *p*, was then slightly opened so that any excess or deficiency of pressure existing within the box acted on the diaphragm, *b*, and caused a slight oscillation of the pointer. This was then brought back to its original position by adjusting the weights in the scale-pan, *K*. It was found that the volume of air passing through the orifice varied as the square root of the weight necessary to bring the pointer back to its position. For the particular apparatus used this may be expressed by the equation:—

Vol. of air in cu. ft. per min. = $10.7\sqrt{\text{grms. in scale-pan.}}$
The results of a number of experiments are given in a table.—W. H. C.

PATENTS.

Gas producers. W. Stewart, Motherwell, N.B., and J. Stewart, Codnor Park, Derby, Eng. Pat. 829, Jan. 14, 1908.

The patent relates to fuel-feeding mechanism for pressure and suction gas producers. A fixed water-cooled casing depending from the top plate of the producer is provided with inclined lateral outlet openings, and with bearings for an inner water-cooled rotating casing. The inner casing, which is provided with a feeding hopper, has outlet openings which register intermittently with the openings in the fixed casing. The fuel falls on to the arms of a water-cooled spreader which is supported from the inner casing of the feeding device and rotates with it. When the device is applied to a suction gas producer, the water spaces are arranged to form the vaporiser or boiler for supplying steam to the producer.—A. T. L.

Gas-producers; Water vessels or vaporisers for —. H. Ries, Munich, Eng. Pat. 966, Jan. 15, 1908.

A VAPORISER for generating steam by means of the heat of the gases leaving a producer consists of a water-vessel having water chambers of rectangular cross-section, which extend downwards and rest on the brickwork of the flue. In another construction, the vaporiser consists of an upper and a lower water chamber connected by four vertical waterways; the lower water chamber rests upon brickwork supports in the flue, arranged so as to allow the hot gases to pass below it as well as between the two chambers.—A. T. L.

Producer gas plants. W. Blakeley, Dowshury, Eng. Pat. 4492, Feb. 28, 1908.

IN a suction gas plant, the top of the scrubber is formed by a water-sealed bell. The variations of the water-level in the sealing-trough cause a more uniform flow of gas through the producer, and the interior of the scrubber can be inspected without breaking joints.—A. T. L.

Gas generators. E. Hanappe, Brussels, Eng. Pat. 15,178, July 17, 1908.

A SUCTION gas producer is provided with a vaporiser arranged around and above the fire-door and open to the space below the grate. An air inlet to the vaporiser and an air inlet, at a lower level, in the ash-pit door are permanently open, so that in the intervals between the suction strokes of the engine there is an up-draught of air through the ash-pit and vaporiser, carrying away the excess of steam. The fire may be poked at any time through the opening in the ash-pit door, and the producer may be worked with low-grade fuel.—A. T. L.

Gas producers. J. J. Bowmer, Newcastle-on-Tyne, Eng. Pat. 20,686, April 1, 1908.

THE patent relates to the provision of a sliding plate at the bottom of a gas-producer, and is specially applicable to the form of producer described in Eng. Pat. 21,682 of 1907 (this J., 1908, 1052). In this form of apparatus, the steam required is generated from the water in the sealing trough at the bottom of the producer. According to the present patent, a sliding plate is arranged below the level of the water in the sealing trough, and is connected with levers by which it can be moved backwards and forwards in order to successively loosen the clinker and cause it to drop into the sealing trough. When the invention is applied to a producer without a water-seal, the sliding plate is in the form of a damper which can be inserted below the fire-grate and above the door of the ash-pit, so that ashes can be removed without interrupting the working of the producer.—A. S.

Gas producer. P. G. Schmidt, Tumwater, Wash. U.S. Pat. 910,319, Jan. 19, 1909.

THE producer chamber comprises a combustion zone in the lower part, separated from a distillation zone in the upper part by a shield, the producer gas being led away from the centre of the shield by a vertical pipe.

The gases formed in the distillation zone are drawn off from the upper part of the producer through a valved down-pipe and are delivered below the grate. The down-pipe passes outside the producer, and is provided with a by-pass leading from a point above to a point below the valve. An exhaustor, driven at a variable speed from a cone belt-pulley, is arranged in the by-pass and may deliver the gases to the down-pipe or direct to the producer-gas main as desired. The temperature of the distillation zone is kept constant by means of a thermostat which controls a throttle-valve in the by-pass and the speed of the exhaustor simultaneously.—A. T. L.

Lighting gas [and coke]; Manufacture of —. A. L. H. Bienaimé and A. Requier. Fr. Pat. 394,311, Nov. 22, 1907.

It is desired to obtain coke free from dust and ready for use without breaking, and to facilitate the discharging of the gas-retorts, the coal is powdered and briquetted with not more than 4 per cent. of tar or other binding agent. The process is applicable to coals which after briquetting are non-caking, and coke-breeze may be treated in the same manner.—A. T. L.

Gas and vapour burners; Incandescent —. A. G. Méker, Nogent sur Marne, France. Eng. Pat. 22,075, Oct. 13, 1904. Under Int. Conv., Oct. 31, 1903.

THE essential features of the new burner are: (1), the exact proportioning of the size of the gas injector hole to that of the air inlet holes, so as to obtain a mixture of the gas with just the precise amount of air required for complete combustion; (2), the special shape of the lower part of the burner and of the mixing chamber, to ensure the correct speed and thorough mixing of the gas and air; and (3), the deep nickel grid at the mouth of the burner to prevent "flashing back" of the flame. A sectional view of the burner is shown in the figure. The gas enters by the side tube, and passes through the hole in the injector piece, I. The air is drawn in

through the large air holes, and mixes thoroughly with the gas as both ascend the tube, B, at the top of which is a brass cap, holding the deep (10 mm.) nickel grid, C. The lower part of the flame yielded by the burner consists of a number of very small blue flames, about 1.5–2 mm. high, each corresponding to one of the passages of the grid; immediately above this zone, the flame is quite homogeneous and of uniform temperature.—A. S.

[Electric lamp filaments] Conductors; Manufacture of refractory —. W. C. Arsem, Schenectady, U.S.A. Eng. Pat. 17,618, Aug. 21, 1908. Under Int. Conv., Aug. 24, 1907.

For the manufacture of refractory conductors for electric incandescence lamps from tungsten or similar metals, the oxides of the metals are mixed with excess of lamp-black, e.g., in the proportion of 18 to 20 parts of carbon to 100 parts of oxide, and the mixture is then heated in a vacuum furnace to 1000° C., the reduced metal being prevented from forming coarse grains by the excess of finely distributed carbon remaining. By burning the reduced metal in air, an oxide in a state of very fine subdivision is obtained. This is subsequently mixed with a quantity of carbon not quite sufficient for reduction and with an agglutinant dissolved in benzene, the solvent being afterwards volatilised by a current of air. The mixture is then squirted through a die of 0.006 inch diameter and $\frac{3}{4}$ inches long, to retain any coarse particles and finally through holes of 0.003 inch diameter, yielding threads suitable for filaments. These threads are covered with talc and baked at 325° to 350° C. and then embedded in pure silica for reduction in a graphite crucible. The oxide being in excess, no carbon remains in the finished filaments and the excess of oxide may be removed by volatilisation.—R. L.

Gaseous fuels; Treatment of — and apparatus therefor. Cie. du Gaz de Lyon, Lyon, France. Eng. Pat. 2720, Feb. 6, 1908. Under Int. Conv., March 1, 1907.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, PETROLEUM, AND MINERAL WAXES.

Petroleum; Analysis of Tschimion —. P. Andrejew. Petroleum, 1908, 4, 207–210.

Tschimion is situated in Fergana, Central Asiatic-Russian territory. The crude oil found here, is a rather thick, dark brown liquid, of sp. gr. 0.872, and decidedly dichroic. It solidifies at -8.5°C ., flashes at -5.5°C . (Abel), and burns at 37°C . The paraffin wax content is 5.14 per cent., and the total content of asphaltic substances, 3.23 per cent., these proportions, in conjunction with the medium sp. gr. and low viscosity, indicating a high content of light fractions ("benzine"). The ultimate analysis gave: carbon, 85.79; hydrogen, 13.65; and ash, 0.02 per cent. Fractional distillation furnished the following products: fraction below 150°C ., 17.75 per cent. (sp. gr. 0.739); 150° – 200°C ., 9 (sp. gr. 0.790); 200 – 250°C ., 8.20 (sp. gr. 0.826); 250° – 300°C ., 19.50 (sp. gr. 0.842); above 300°C ., 40.40 (sp. gr. 0.8986); residue, 3.00; loss, 2.14 per cent. The crude oil is capable of yielding up to 6 per cent. of light distillate boiling below 100°C ., up to 5.5 per cent. boiling between 100° and 125°C ., and 4.7 per cent. of heavy "benzine" (b. pt. 125° – 150°C .). The refined lamp oil fractions are of good quality, having the sp. gr. 0.8185, viscosity, 1.2 at 18°C .; and flashing point, 29.5°C . The higher fraction, above 300°C ., is very thick, contains up to 12 per cent. of paraffin wax, and has the viscosity 7.3 at 50°C . A tendency to decomposition is exhibited during fractional distillation, the fraction distilling at 200° – 225°C . showing a reddish tinge, and the higher fractions ranging from wine-yellow to dark brown with greenish fluorescence. The iodine value of the fractions distilling between 200° and 250°C . is 3, increasing to 9.6 in the next higher fraction, and to 29.3 above 300°C . The analysis of the fractions between 150° and 160°C . gives results corresponding to the formula, $\text{C}_{20}\text{H}_{22}$. In utilising Tschimion oil, attempts were made at first to employ the fractions above the lamp oil series as fuel, but without success; and a similar result attended the endeavour to employ it for the same purpose after the removal of the lightest fractions only, the residue being too thick on account of its high paraffin wax content, so that the latter had also to be eliminated.—C. S.

Petroleum products; Fundamental errors in the manufacture of — in Roumania. R. Wischin. Monit. Pétrole, Roumain, 1908, 865; Petroleum, 1908, 4, 210.

IN the Roumanian petroleum industry, owing to lack of experience, the methods of treating the oil were founded on a wrong basis, without sufficient consideration of

the peculiarities of the crude oil. This oil needs special care in distillation, owing to the presence of constituents that decompose at high temperatures, and of others that polymerise under these conditions, especially when the vapours of the distillates are exposed to heat. The best method of counteracting these tendencies is by continuous distillation, in small stills kept filled to a given height, the vapours being allowed to escape freely. The proper fractionation of the distillates, by means of suitable dephlegmating columns, is also important; and for this purpose the friction type of dephlegmator is preferable, the heavy vapours being condensed by contact with the sharp corners of the apparatus, whilst the lighter vapours, remaining uncondensed, escape.—C. S.

PATENT.

Petroleum and related oils; Desulphurising Lima or analogous —, C. A. Robinson, West New Brighton, N.Y., Assignor to Standard Oil Co., Bayonne, N.J. U.S. Pat. 910,584, Jan. 26, 1909.

The distillate of sp. gr. below 0.865 from the oil is treated with sulphuric acid of more than 60° B., in the proportion of not more than 60 lb. of acid per barrel of oil, the initial temperature of the mixture being kept below 66° F.—A. S.

IV.—COLOURING MATTERS AND DYESTUFFS.

PATENTS.

Halogenised vat-dyestuffs; Manufacture of —, O. Murray, London. From Soc. of Chemical Industry, Basle, Switzerland. Eng. Pat. 8530, April 16, 1908. Addition to Eng. Pat. 6106 of 1907 (this J., 1907, 1194).

VALUABLE halogen derivatives of indirubin may be obtained by condensing a halogen-isatin derivative of the benzene or naphthalene series with indoxyl or one of its derivatives, or, if it is desired to obtain products halogenised only in the indoxyl radical, by causing a halogen-indoxyl or one of its homologues to act on isatin or one of its homologues or analogues. The dyestuffs thus obtained dye cotton in an alkaline hydrosulphite vat, giving red-violet, blue-violet, and blue tints of excellent fastness. Example: A solution of 31 parts of indoxyl in 4000 parts of water is poured quickly into a solution of 72 parts of dibromoisatin and 13 parts of sodium carbonate in 3000 parts of water, care being taken to stir well. The whole is then very rapidly heated to the boil and kept boiling gently for 2 hours, the mixture being kept neutral by the addition of sodium carbonate if necessary. The mass is then allowed to cool and the precipitated dyestuff is filtered off, washed, first with dilute sodium hydroxide solution and afterwards with hot water, and finally pressed and dried. The dried dyestuff is a brown-red powder which dissolves in concentrated sulphuric acid to a brown-violet solution and in hot nitrobenzene to a red-violet solution from which it crystallises as brown-red needles. In an alkaline hydrosulphite vat, the dyestuff dyes cotton red-violet shades.—P. F. C.

Sulphur dye or colour [Sulphide dyestuff] and process of making same, E. S. Chapin, New York. U.S. Pat. 909,151—909,156, Jan. 12, 1909.

(1). Wood sawdust is heated with sulphur and sodium sulphide until a non-hygroscopic, readily pulverisable dyestuff is formed. The product dyes cotton in fast dark yellowish-brown shades. (2). Claim is made for a sulphide dyestuff produced by heating starch with a colour-forming, aromatic chemical, sulphur, and sodium sulphide. (3). Claim is made for the process of producing dyestuffs by heating a carbohydrate or non-crystallisable polysaccharide with *m*-phenylenediamine and sulphurising substances containing an excess of sulphur. (4). By heating salicylic acid with sulphur and sodium sulphide, a dyestuff is produced which dyes cotton in "fast golden brown bronze" shades. (5). The dyestuff produced by heating together starch, sulphur, sodium sulphide, and copper sulphate dyes cotton in an alkaline bath fast "olive

brown black shades." (6). The dyestuff produced by heating together starch, *m*-phenylenediamine, copper sulphate, sulphur, and sodium sulphide dyes unmodified cotton in an alkaline bath reddish-catch brown shades.—J. C. C.

Sulphur colour [Sulphide dyestuff] and process of making same, E. T. Bundsman, Assignor to The Point Loma Chemical Co., Point Loma, Cal. U.S. Pat. 909,277, Jan. 12, 1909.

THE dyestuff produced by heating together grape sugar, *m*-nitroaniline, and sulphurising agents, dyes cotton in an alkaline bath, fast brown shades.—J. C. C.

Anthracene dyestuffs; Process for preparing blue —, Farbwerke vorm. Meister, Lucius, and Brüning. Ger. Pat. 205,551, Jan. 26, 1908. Addition to Ger. Pat. 205,096, Nov. 30, 1907.

1,4-AMINOHYDROXY- and 1,4-alkylaminohydroxyanthraquinone-*a*-sulphonic acid are reduced to stable leuco-compounds by means of hydrosulphite, etc., in alkaline solution. These leuco-compounds, when heated with monoalkylamines, are converted into blue dyestuffs analogous to those described in the principal patent (see this J., 1909, 86).—T. F. B.

Disazo dyestuffs; Process for preparing red —, Farbwerke vorm. Meister, Lucius, and Brüning. Ger. Pat. 205,661, June 3, 1906. Addition to Ger. Pat. 204,102, April 26, 1906.

DIAZO compounds are combined with *p*-aminobenzoyl-2,5,7-aminonaphtholsulphonic acid; this dyestuff is diazotised and combined with an aminoacyl-2,5,7-aminonaphtholsulphonic acid, in which the aminoacyl group is attached to the amino-group. The dyestuffs produced are soluble in water, and dye unmodified cotton in red shades.—T. F. B.

Disazo dyestuffs; Process for preparing yellowish-red to bluish-red —, Farbwerke vorm. Meister, Lucius, and Brüning. Ger. Pat. 205,663, April 26, 1906. Addition to Ger. Pat. 204,102, April 26, 1906.

A DIAZO compound is combined with *m*-aminobenzoyl-2,5,7-aminonaphtholsulphonic acid, and the product is diazotised and combined with 2,5,7-aminonaphtholsulphonic acid, its *N*-acyl derivatives, or its unsymmetrical thiourea derivative.—T. F. B.

Disazo dyestuffs; Process for preparing yellowish-red to bluish-red —, Farbwerke vorm. Meister, Lucius, and Brüning. Ger. Pat. 205,665 and 205,666, May 7, 1907. Additions to Ger. Pat. 204,102, April 26, 1906.

THE monoazo dyestuffs obtained by the combination of diazonium compounds with *p*- or *m*-aminobenzoyl-2,5,7-aminonaphtholsulphonic acids, are further diazotised and combined with pyrazolones or their sulphonic or carboxylic acids.—T. F. B.

Trisazo dyestuffs; Manufacture of —, P. A. Newton, London. From Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. Eng. Pat. 5484, March 11, 1908. Addition to Eng. Pat. 14,248, June 20, 1907.

SEE Ger. Pat. 202,117 of 1907; this J., 1908, 1148.—T. F. B.

Naphthylpyrazolonesulphonic acid, P. Volkmann, Assignor to Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. U.S. Pat. 910,437, Jan. 19, 1909.

SEE Fr. Pat. 391,456 of 1908; this J., 1908, 1148.—T. F. B.

Colouring matters [azo dyestuffs] suitable for use in the form of their lakes; Manufacture of —, J. Y. Johnson, London. From Badische Anilin und Soda Fabrik, Ludwigshafen on Rhine, Germany. Eng. Pat. 11,878, June 1, 1908.

SEE Fr. Pat. 391,155 of 1908; this J., 1908, 1148.—T. F. B.

Thioindigo leuco compounds; Process of making —, E. Münch, Assignor to Badische Anilin und Soda Fabrik, Ludwigshafen on Rhine, Germany. U.S. Pat. 910,839, Jan. 26, 1909.

SEE Fr. Pat. 385,044 of 1907; this J., 1908, 497.—T. F. B.

α-Isatin anilide and its homologues with sulphurous acid; Process of producing compounds of —. C. Stephan and A. Rahtjen, Hamburg, Germany. Eng. Pat. 13,499, June 25, 1908.

SEE Ger. Pat. 204,478 of 1907; this J., 1909, 86.—T. F. B.

Azo lake and process of making same. E. Ulrichs, Elberfeld, Assignor to Wülffing, Dahl, und Co., Barmen, Germany. U.S. Pat. 910,030, Jan. 19, 1909.

SEE Fr. Pat. 381,206 of 1907; this J., 1908, 132.—T. F. B.

Indigo; Process for preparing bromo-derivatives of —. Cie. Paris. de Couleurs d'Aniline. Addition, dated Nov. 29, 1907, to Fr. Pat. 322,348, June 14, 1902.

SEE Eng. Pat. 26,275 of 1907; this J., 1909, 17.—T. F. B.

V.—PREPARING, BLEACHING, DYEING, PRINTING, AND FINISHING TEXTILES, YARNS, AND FIBRES.

Silk fabrics; Deterioration of weighted —. P. Sisley. Rev. Gen. Mat. Col., 1909, 13, 33–43.

THE only objection to the moderate weighting of silk fabrics is their subsequent deterioration, and the author now publishes the results of his ten years' research into the causes and prevention of this fault. The weighting of dyed silks, which reduces their elasticity, but has little or no effect on their initial strength, consists in fixing tin or aluminium silico-phosphate on the fibre, which it surrounds with a composition similar to enamel, both physically and chemically. This coating according to Meister is liable to devitrification just as enamels are, while a rise of temperature may cause tendering of a purely physical character owing to the different coefficients of expansion of the fibre and the coating. Another cause is dehydration; for heavily weighted silk exposed to a temperature of 120° C. for ten minutes lost its strength nearly completely, though it regained it again on re-absorbing its hygroscopic moisture. By drying at 180° C. the same silk became quite rotten. Gnehm and Baenziger having shown that exposure to a temperature of 40° C. produces no change and to one of 55–65° C. very little, Meister published the hypothesis that all deterioration was physical in character, stating that on extracting a tendered pattern with hydrofluoric acid, the strength of the fibre was restored. The author, however, found in all cases that though the fibre did resume a little of its elasticity, a great deterioration remained, and he shows that there are other causes than physical ones. It is well-known that even a moderately weighted fabric is susceptible to deterioration in the sunlight, and according to Gnehm and Baenziger, patterns weighted to 120–150 per cent. were completely tendered by exposure to the sun for 8 days, while the author has found that diffused daylight caused tenderness proportional to the intensity of the light. Experiments with several different methods of weighting showed that the old stannic hydroxide weighting was much more susceptible to light than that consisting of silico-phosphates, and that deterioration took place in all cases, appearing to be proportional to the quantity

of stannic oxide enveloping the fibre before exposure. The deteriorated fabrics were analysed and every one was found to contain a notable proportion of stannous oxide, which was not present in the unexposed portions. The author concludes from this that the stannic hydroxide acts as a catalytic agent, becoming reduced by the action of light and taking up oxygen again from the air, and that it is the oxygen liberated which tenders the fibre by a process of slow combustion. This does not take place without the aid of light, for different patterns weighted by the same method were not found to deteriorate to the same degree when kept in darkness. Most silk fibre contains both iron and copper in sufficient quantities to act catalytically and experiments showed that the proportion of iron had a slight, and that of copper a very marked, influence on the deterioration. It was shown by experiment that tendering only takes place in the presence of air and moisture and that it increases with the percentage of weighting and with the temperature, while, as the author has previously proved, traces of sodium chloride (always present in industrial water) have a certain deteriorating influence. In order to prevent deterioration altogether, a substance must be incorporated with the weighting which is colourless, inodorous, and non-poisonous and which has energetic anti-oxidation and anti-catalytic properties. Both Meister and Gianoli advocated impregnation with alkali thiocyanates. The employment of these substances presents practical difficulties which the author claims to have overcome by substituting thiocarbamides. A large number of experiments in which the patterns were impregnated with a 3 per cent. solution of thiocarbamide were uniformly successful in preventing deterioration under the influence of light, heat, and storing in darkness. The process which has been applied with invariable success is known under the name: "Traitement T.S."—H. P. P.

Calico printers; Cheap blues for —. E. Steiner. Rev. Gen. Mat. Col., 1909, 13, 44.

THE goods are printed with a reserve of citric acid either alone or mixed with tartaric acid; padded in aluminium acetate suitably thickened; steamed, washed, treated in a bath of cow's dung and sodium arsenite or phosphate; washed again, treated in a tannin or sumac bath, again washed, dyed with a basic blue dyestuff, and finally soaped and chlorinised. For deeper blues, iron acetate is added to the padding bath.—H. P. P.

Aniline Black; Use of an insoluble vanadium salt for printing —. G. Friedlander. Rev. Gen. Mat. Col., 1909, 13, 44–45.

AS catalysing agent in printing Aniline Black, copper sulphide, introduced by Lightfoot, is unsatisfactory because it becomes oxidised to sulphate, thus rendering the bath unstable, while the chromium tungstate proposed by Higgin causes the objectionable deposit of red tungstic chloride. The use of vanadium salts discovered by A. Gayard and G. Witz effects economy, very small quantities being necessary on account of their great activity; but these salts tend to the formation of black in the printing colour by reason of their solubility. The author has overcome this difficulty by employing insoluble lead metavanadate which is only dissolved by the hydrochloric acid liberated on steaming the goods. The substance is prepared by precipitating a 0.1 per cent. solution of vanadium chloride with lead acetate until the supernatant liquid remains colourless. The mixture, containing lead metavanadate in suspension, is used in the proportion of a few tenths of a milligramme for every kilogramme of the printing colour.—H. P. P.

Colouring matters [dyestuffs]; Identification of — in dyed cotton fabrics. G. E. Holden. J. Soc. Dyers and Col., 1909, 25, 47–53.

THE author uses as reagents (1), chloroform, recommended by Lenz in 1887 as a good solvent for Indigo; and (2), titanous chloride, the use of which was first suggested by Knecht in 1904. *Test for Indigo in compound shades.*—A small piece of the dyed pattern is warmed gently with chloroform: the presence of Indigo is indicated by the

blue coloration of the solvent. In all of the following groups, direct dyestuffs whether fixed by after-treatment or not, sulphur dyestuffs, mineral dyestuffs, and mordant dyestuffs are insoluble in chloroform. The test is directly applicable if the cotton has been slightly topped with basic dyestuffs, but if excessive quantities of these latter be present, they must be removed by boiling in methylated spirit containing a few drops of hydrochloric acid.

Reds.—(1). A piece of the pattern is immersed in cold chloroform. Basic reds, when fully fixed, give no coloration. The solution is coloured an intense amber by Paranitraniline Red, reddish-orange by Paranitro-orthoanisidine, Azo Pink BB, and Chloranisidine, and red by Thioindigo Scarlet R. Any coloration given by incompletely fixed basic reds can be easily distinguished from the others. (2). Direct dyestuffs are identified by the "bleeding" which occurs when a piece of the fabric is boiled with water. (3). With boiling titanous chloride solution, developed direct reds are discharged to a white or yellow colour, basic reds to a dull yellow or brown, and Alizarin Red to a maroon colour. (4). A piece of the pattern is wetted, immersed in bleaching powder solution of 5° T., and acetic acid added gradually. Azo Pink BB is discharged at once to a bright yellow-orange; Chloranisidine Red is discharged only very slowly or on addition of a comparatively large quantity of acid; Paranitro-orthoanisidine is not affected. **Pinks.**—Cold chloroform is coloured yellow by Paranitraniline and reddish-orange by Paranitro-orthoanisidine and Azo Pink BB; the two latter are distinguished as described under "Reds." Rhodamine on tannin, chrome, or alumina mordants generally gives a delicate fluorescent tint with chloroform, but can also be detected by any of the well-known tests. **Bordeaux or Claret shades.**—(1). Cold chloroform is coloured an intense red by α -Naphthylamine Claret, an intense amber by Paranitraniline red and Direct Blue mixture, brownish-red by Indanthrene Claret G, red, with fluorescence, by Thioindigo Red B and Vat Red B, and red-violet by Helindone Red 3B. No coloration is produced by basic clarets, when thoroughly fixed. (2). On boiling the pattern with water, direct clarets are recognised by "bleeding." (3). With boiling titanous chloride solution, developed clarets are completely discharged, with the exception of Primuline, which leaves a yellow colour. Sulphur clarets evolve hydrogen sulphide. Alizarin Bordeaux is reduced to a dirty brown. Basic clarets are discharged to a dull yellow or brown. **Violets.**—(1). With cold chloroform, Indanthrene Violets and Thioindigo Red B and Indigo mixture give reddish-violet fluorescent solutions, Ciba Violet B gives a blue-violet solution, and Ciba Violet R, a red-violet solution. Basic violets give no coloration when thoroughly fixed with tannin; colorations from incompletely fixed basic violets can be easily recognised. (2). On spotting with concentrated nitric acid, Indanthrene violets give a grey to black, and Thioindigo Red B and Indigo mixture, a red spot. (3). Direct, basic, and sulphur violets and Alizarin Violet can be distinguished by tests similar to those used for "Clarets." **Browns.**—(1). On immersing the pattern in cold chloroform, brown colorations are produced by Para Brown G and R, developed with "diazo para," an amber colour is yielded by Para Red with direct or coupled blacks and with Aniline Black, a red by benzidine on α - or β -naphthol, and a bluish-red by tolidine on α - or β -naphthol. (2). The direct dyes are recognised by "bleeding" on boiling with water. (3). With boiling titanous chloride solution, direct browns, developed, coupled, etc., are decolorised, basic browns are discharged to a dull yellow to brown tint, sulphur browns evolve hydrogen sulphide, Catechu Brown is scarcely affected, Para Red with direct or coupled blacks first becomes red and is then gradually decolorised, Para Red with Aniline Black is slowly discharged to a brownish-black, becoming black on exposure, and Iron Buff is decolorised and can be further identified by testing for iron. **Yellow and orange dyes.**—(1). Cold chloroform is coloured yellow by Indanthrene yellows and Algole yellows, reddish-orange by Algole Orange R, and an intense orange by metanitraniline and nitrotoluidine developed on the fibre. Developed Primuline, Indanthrene Orange RT,

and basic colours, when fully fixed, give no coloration. (2). Direct, basic, and sulphur yellows are identified as described under "Clarets." (3). With boiling titanous chloride, Indanthrene yellows become blue; Algole yellows are scarcely affected; Primuline developed with phenol or resorcinol becomes bright yellow, and can subsequently be diazotised and developed with β -naphthol to a red; Primuline treated with hypochlorite is reduced to a brownish colour and cannot be diazotised and developed. Indanthrene Orange RT is reduced to a characteristic orange tint. (4). On spotting with ammonium sulphide, Chrome Yellow and Orange are coloured black. (5). Alizarin colours are recognised by testing for the mordants. **Greens.**—(1). Cold chloroform is coloured greenish-blue by Indanthrene Green B, olive-green by Algole Dark Green B, bright yellowish-green by Indanthrene Blue RS and Indanthrene Yellow mixture, and green by some fully fixed basic greens such as Brilliant Green and Malachite Green. Some basic greens, Algole Green B, and Russian Green, etc., on iron mordant, give no colorations. (2). With boiling titanous chloride solution, direct greens, coupled greens, etc., are decolorised, basic greens are discharged to a dull yellow or brown, sulphur greens evolve hydrogen sulphide, Algole Green B gives a reddish-blue or blue colour, Indanthrene Green B gives a Grenat colour, Algole Dark Green B, a reddish-brown, and Indanthrene Blue RS and Indanthrene Yellow mixture, a dirty blue to violet colour; Russian Green, Fast Green O, etc., on iron mordant are discharged and may be further recognised by testing for iron. **Blues.**—(1). With cold chloroform, Indigo Blue, Ciba blues, Indanthrene Blue RS, Algole Blue 3G, and Algole Blue CF give blue colorations, Dianisidine Blue gives a violet, Indanthrene Blue RC gives a blue violet, with fluorescence, and Indanthrene Dark Blue BO gives a bluish-green coloration with a red fluorescence. (2). With boiling titanous chloride, Alizarin Blue gives a brownish-black colour becoming bluer on exposure to air; Indigo Blue is decolorised, very dark shades leaving an olive to blue tint; Ciba blues give a green to olive colour; Algole Blues 3G and CF are reduced to black and Grenat colours respectively. (3). On spotting with strong nitric acid, Ciba blues give a brown spot which gradually changes to a light dirty blue tint; Indigo gives a yellow spot surrounded by a green rim. Direct blues, basic blues, and sulphur blues are identified as described under "Clarets." **Blacks.**—(1). With cold chloroform, Azophor blacks give red-violet to blue-violet solutions; other blacks are insoluble. (2). With boiling dilute hydrochloric acid, a red or orange solution is obtained with Logwood Black. (3). With boiling titanous chloride, direct, developed, and coupled blacks are decolorised; basic blacks give a dull yellow to brown colour; sulphur blacks evolve hydrogen sulphide; Aniline Black and Diphenyl Black become brown; chrome mordant dyes give a brown to brownish-black colour. (4). A piece of the pattern is immersed in bleaching powder solution of 5° T., a small quantity of acetic acid is added, and after standing, the liquid is poured off, and the fabric soured with cold acetic acid and washed. With chrome mordant dyestuffs, the fibre is coloured yellow to yellowish-brown; it is subsequently tested for chromium. An olive to green coloured fibre is obtained with prussiate Aniline Blacks, and a red-brown with other Aniline Blacks and Diphenyl Black.

For printed fabrics, tests for mordants should always be made, viz., for iron and aluminium by first discharging the colour with bleaching powder solution and acetic acid, and then boiling with logwood solution; and for chromium by fusing with sodium carbonate and potassium nitrate. In the following table are given the reactions of a number of dyestuffs with titanous chloride and with bleaching powder solution of 5° T. to which a little acetic acid has been added. Most basic dyes are reduced by titanous chloride, with production of brown titanium tannate; Indanines leave a blackish coloured fibre. When using titanous chloride for testing light and medium shades of sulphur colours, the solution must first be boiled after addition of a small quantity of hydrochloric acid, in order to remove traces of hydrogen sulphide, which are frequently present.

	Titanous chloride.	Bleaching powder solution and acetic acid.
Algoe Blue CF	Grenat	Green
Algoe Blue 3G	Dirty drab	Gradually discharged
Algoe Dark Green B	Reddish-brown	Light yellow-brown
Algoe Green B	Reddish-blue	Discharged
Algoe Red B	Brown	Gradually bleached to salmon shade
Alizarin Blue	Dirty black	Discharged
Alizarin Red	Maroon	Discharged
Azo Pink 3B	Discharged	Discharged
Bromindigo FB	Olive	Weakened in shade
Chloranisidine	Discharged	Very slowly discharged
Ciba Blues	Olive	Weakened in shade
Ciba Red B	Discharged	Unaffected
Ciba Violet B	Discharged	Gradually weakened
Ciba Violet R	Discharged	in shade
Helindone Red 3B	Dirty violet	Unaffected
Helindone Red 3B with Indigo	Dirty	Red-violet
Indanthrene Blue BO	Reddish-brown	Black in shade
Indanthrene Blue BT	Black	Black in shade
Indanthrene Blue RC	Grenat	Bluish-green
Indanthrene Blue RS	Maroon	Green
Indanthrene Claret G	Brown	Becomes gradually browner
Indanthrene Green B	Grenat	Dirty brown
Indanthrene Red R	Reddish-brown	Becomes a shade "brickier"
Indanthrene Violet R	Grenat	Dirty in shade
Indanthrene Violet RT	Maroon	Redder in shade
Indigo Blue	Yellow tint	Discharged
Paranitraniline Red	Discharged	Unaffected
Paranitro-orthoanisidine	Discharged	Unaffected
Thioindigo Red B	Practically discharged	Slowly weakened in shade
Vat Red B	Bluer, then discharged	Red colour

PATENTS.

Threads or filaments from cellulose; Manufacture of — W. P. Dreaper, Felixstowe. Eng. Pat. 858, Jan. 14, 1908.

CELLULOSE is converted into hydrocellulose either by treating it with a strong solution of sodium hydroxide, (but without any bleaching process as at present practised, in order to prevent oxidation), or by steeping it in a solution of zinc chloride of 10° T. and then heating. The hydrocellulose thus obtained is dissolved in a solution of zinc chloride, which may be made distinctly acid to facilitate the solution, though if this be done it is subsequently necessary to neutralise the acid with zinc oxide. The solution of hydrocellulose is then treated in a vacuum at a suitable temperature to remove air bubbles and filtered. It is then forced through fine openings into a coagulating bath which may consist of:—(a), a strongly alkaline solution to which ammonium chloride and ammonia may be added to prevent the precipitation of zinc compounds; (b), a strong solution of a suitable salt such as sodium sulphate; (c), a mixture of alcohol and water. The threads prepared in this way may be mercerised and are then washed and dried, certain advantages being obtained if the drying is effected in a partial vacuum.—P. F. C.

Degreasing and cleaning fabrics, yarns, carpets, and like materials; Apparatus for — E. G. Scott, London. Eng. Pat. 27,006, Dec. 6, 1907.

THE apparatus comprises a large chamber divided into two parts by a horizontal partition, the lower part being used as a grease-extracting chamber, whilst the upper part is employed for drying the cleansed material. Endless bands, between which the goods to be cleaned are gripped, travel through the whole apparatus. On emerging from the drying chamber they divide so as to permit of the removal of the goods, but meet again just before the point of entry into the machine. The extracting chamber is provided with a number of rollers over and under which travel the endless bands carrying the material, which is thus exposed to the action of the hot or cold benzene, naphtha, etc., or other liquid employed as solvent. This extracting chamber is also divided into compartments by means of partitions and the solvent is made to travel from one com-

partment to another through pipes, the direction of flow being opposite to that in which the material is travelling. Before leaving the extracting chamber, the endless bands pass through the nip of a pair of squeezing rollers in order to remove as much as possible of the solvent from the goods. The drying chamber is also provided with a number of guide rollers. In order to vaporise, remove, and subsequently recover the solvent from the material, the drying chamber is placed within a system which also comprises an apparatus for heating air, a condenser for cooling it and separating the condensed solvent, and a fan for producing the circulation of the air through the system. The air passes through the heater into the drying chamber, becomes saturated with solvent during its passage through it, and is drawn by the action of the fan into the condenser where the solvent is condensed, the air being again circulated by the fan, and the cycle being repeated as often as is necessary. The solvent which leaves the extracting chamber is distilled to recover the grease and then used again.—P. F. C.

Scouring textile fabrics; Machines for — J. Bailey, Slaithwaite, Yorks. Eng. Pat. 444, Jan. 8, 1908.

IN the present scouring machines, the upper squeezing roller rests by its own weight on the lower one and is driven from it by friction. In practice the upper roller is liable to slip on the travelling fabric. This defect is remedied by the two following improvements. (1). The shaft of the upper roller is journaled in bearings in blocks which are capable of sliding vertically in slots in the sides of the machine. A strong spiral spring is confined in each slot between the block which holds the upper roller and a second block or plate which is fastened on its upper side to a screw which can be raised or lowered. By these means, the pressure of the upper squeezing roller on the lower one can be adjusted at will. (2). The axes of the squeezing rollers are provided with similar pulleys, and by means of an endless belt which passes over them and around suitable intermediate carrier pulleys, a positive rotary motion is transmitted from the lower to the upper roller.—P. F. C.

Paper, fabric, and other surfaces; Method and apparatus for spraying colour and other liquids on to — C. L. Burdick, Wood Green, Middlesex. Eng. Pat. 721, Jan. 11, 1908.

HITHERTO in machines of the kind described in Eng. Pats. 7344 of 1902, 8703 of 1903, and 4211 of 1905 (see Fr. Pat. 328,714 of 1903; this J., 1903, 994) in which the belt drives the stencil and thus both travel at the same speed, the stretch of the apron and of the material when leaving the stencil had in some cases a tendency to allow the wet surface of the material to soil the face of the stencil and so make a smudge when the stencil again came into contact with the material. This difficulty is avoided by driving the stencil by a friction gear, the proportions of which are such that the stencil travels rather quicker than the material under treatment. A further improvement is produced by separately driving in a variable manner the rotary device controlling the air and colour valves. Surplus colour is removed from the stencil by means of a suction apparatus in connection with a casing having a mouth arranged so as to make close contact with the stencil.—P. F. C.

Printing of textile fabrics. The Calico Printers' Assoc., Ltd., Manchester, and E. Schofield, Lennoxtown. Eng. Pat. 6970, Mar. 30, 1908.

CERTAIN acids and acid salts may be added to the customary diazo printing colours in an amount sufficient to resist other colours without interfering with the fixation of the corresponding azo colours by the combination of the diazo compound with the naphthol of the "prepare." Citric acid, phosphoric acid, and acid citrates are the acids and acid salts which can be used for this purpose. Example:—A solution of 12 parts of citric acid in 27 parts of water is thickened with starch, and 8 parts of a 33 per cent. solution of sodium hydroxide are added. 4 parts by volume of this paste are mixed with 1 part by volume of a solution of *p*-nitro-diazobenzene hydrochloride in which the free mineral acid has been neutralised by the

addition of sodium acetate and of such concentration that a gallon of the solution contains the diazo compound from 20 oz. of paranitraniline. The resist printing colour thus obtained is printed on to the fabric which has previously been padded with an alkaline solution of β -naphthol, containing 4 oz. of sodium acetate in a gallon, and dried. The printed fabric is next dried, padded or over-printed with a suitable mordant such as aluminium acetate, then aged or steamed and afterwards fixed and dyed in the ordinary way. A second example is given for the production of fast azo colours under indigo.—P. F. C.

Printing blue, violet to lilac coloured tints fast to washing and light; Process for producing in —. O. Imray, London. From Soc. of Chemical Industry, Basle, Switzerland. Eng. Pat. 19,310, Sept. 14, 1908.

By printing with a mixture of indigo and polyhalogen derivatives of indigo or indirubin or halogen substitution products of dyestuffs of the thioindigo series, tints are produced of excellent fastness to washing and light. The mixtures have moreover the advantage that they can be used for printing without caustic alkalis since the presence of alkali carbonate suffices for complete reduction and fixing.—P. F. C.

Discharging indigo dyings by means of formaldehyde-hydrosulphite or formaldehyde-sulphoxylate; Process of —. M. Schwarz. Ger. Pat. 204,565, Feb. 27, 1907.

THE discharge paste containing the reducing agent and also a primary, secondary, or tertiary amine, is printed on the indigo-dyed fabric, which is then steamed, and the indigo white washed out of the fabric. It is said that the fibre is not weakened by the process, nor are the copper rollers attacked.—T. F. B.

VII.—ACIDS, ALKALIS, SALTS, AND NON-METALLIC ELEMENTS.

Sulphuric acid; Some mixed anhydrides of —. A. Pictet and G. Karl. Bull. Soc. Chim., 1908, 3, 1114–1126.

BESIDES the mixed anhydride of sulphuric and nitric acids, previously described (this J., 1907, 923), the authors have prepared similar mixed anhydrides of sulphuric acid with nitrous, boric, and chromic acids. The mixed anhydride of sulphuric and nitrous acids is prepared by mixing together solutions of the components in carbon tetrachloride. It has the composition, $(SO_3)_2(N_2O_3)_2$, melts at 198° – 200° C., and boils at 362° – 365° C. Two mixed anhydrides of sulphuric and boric acids were obtained, viz., $(SO_3)(B_2O_3)$ and $(SO_3)_2(B_2O_3)$, by heating the components together in sealed tubes. On heating above 100° C. they are dissociated. By heating the boryl disulphate with the corresponding alcohols, the authors

prepared methyl borate (b.pt. 65° C.), ethyl borate (b.pt. about 118° C.), and amyl borate (b.pt. 255° C.). Chromyl sulphate, $(SO_3)(CrO_3)$, was prepared by heating together chromic anhydride and sulphuric anhydride in a sealed tube at 75° C. It is easily decomposed on heating, with formation of chromium sulphate and oxygen.—A. S.

Pyridine in strong ammonia solution; Detection and determination of —. G. Pinchbeck. Pharm. J., 1909, 82, 84–85, 177.

Detection.—Fifty c.c. of the ammonia solution are diluted, then neutralised with hydrochloric acid. The cool liquid is rendered alkaline with sodium hydroxide, and then shaken with 10 c.c. of chloroform. The chloroform extract is filtered and divided into two portions. To one, 0.25 c.c. of strong hydrochloric acid and 2 drops of a 2 per cent. solution of bromine in chloroform, are added. The crystalline bromo-compound, $C_5H_5NBr_2$, is precipitated if only a small amount of pyridine be present. The other portion is exposed to a current of warm air, when the residue left will have the characteristic odour of pyridine, if that base be present. *Determination.*—100 c.c. of the ammonia solution, diluted with an equal volume of water, are carefully neutralised with dilute sulphuric acid. The cool solution is then made alkaline with sodium hydroxide, diluted to 400 c.c. with distilled water, and distilled until one-third has passed over. The distillate is treated with 10 grms. of mercuric chloride, dissolved in 150 c.c. of distilled water. The precipitate is collected, and washed with cold 92 per cent. alcohol, which removes the pyridine-mercuric chloride compound. The alcoholic filtrate is carefully neutralised, diluted to 400 c.c., and again slowly distilled. The distillate should not require for neutralisation more than 2 c.c. of N/10 sodium hydroxide solution, with methyl orange indicator. This is equivalent to 0.00948 per cent. of pyridine.—J. O. B.

Felspar; Decomposition of — by water. W. Funk. Z. anorg. Chem., 1909, 22, 145–146.

CUSHMANN (this J., 1907, 608) effected the extraction of alkalis from felspar by electrolysis under specified conditions, but the author has studied the effect of water alone. The quantity of alkali dissolved, depends on the surface and the time of contact. When felspar, ground to a fine powder in the dry state and passed through a sieve with 800 holes per sq. cm., is suspended in water, the coarser particles rapidly sink to the bottom, but a considerable proportion remains suspended for weeks, the upper layers becoming opalescent. The particles remaining in suspension no longer consist of pure felspar, but are partly composed of colloidal decomposition products. An analysis of the separated colloid, after drying at 120° C., showed: water, 5–15; silica, 40–60; aluminium oxide, 11–18; potassium oxide, 17–22 per cent. The original felspar contained 12.8 per cent. of potassium oxide and 2.3 of sodium oxide. The suspended matter is a negative colloid which is readily flocculated by traces of acid. The liquid contained in the state of true solution only 0.1–0.2 per cent. of the total alkali of the felspar and mere traces of silica and alumina. Felspar which has been coarsely broken in the dry state may be ground to a fine powder in presence of water for 12 hours without forming a colloidal suspension. The decomposition of the felspar in the above experiments was not confined to its finest particles; even the heavier particles of the sediment, when stained with "methylene blue," showed a blue-coloured zone of decomposed mineral around a centre of unchanged felspar. Ground felspar, when shaken with water, gives a solution which is coloured pink by phenolphthalein, and if this alkalinity be neutralised, the pink colour gradually returns owing to further decomposition. Fused felspar decomposes far more readily than the ordinary. If carbon dioxide be passed at intervals through a suspension of felspar in water, a point is ultimately reached when the solid matter settles completely, leaving a clear liquid. This liquid was found to contain 0.7 per cent. of the total alkali in the case of ordinary felspar and 1.1 per cent. in the case of fused felspar. In practice, ground felspar shows far less tendency to "cake" in waters rich in carbon dioxide than when ordinary water is used for mixing.—J. F. B.

Calcium phosphide: Rapid preparation of —. for obtaining phosphine. C. Matignon and R. Trannoy. Compt. rend., 1909. 148, 167—170.

CALCINED calcium phosphate (232.5 parts) in fine powder, is intimately mixed with aluminium powder (108 parts) ($3\text{Ca}_3(\text{PO}_4)_2 : 8\text{Al}_2$), heated to redness, and then ignited. The resulting mixture of alumina and calcium phosphide is very uniform. To prepare phosphine from it, it is broken up and placed in a flask provided with a dropping funnel and delivery tube, and water is added. When the evolution of gas slackens, hydrochloric acid is gradually added till reaction is complete. The gas evolved, when the air has been expelled from the vessel, contains 96—97 per cent. of phosphine, the only impurity being hydrogen. (See also this J., 1900, 667.)—J. T. D.

Sulphur dichloride: Reaction of —, on metallic oxides. F. Bourion. Compt. rend., 1909. 148, 170—171.

THE simultaneous reaction on metallic oxides of sulphur dichloride and chlorine (this J., 1904, 441) yields in many cases a mixture of chloride and oxychloride, the latter being difficult or impossible to decompose. If sulphur dichloride be used alone, and be volatilised over the metallic oxide contained in a boat in a heated glass tube, the excess of sulphur dichloride being retained by condensing arrangements at the far end of the apparatus, chlorides free from oxychloride are much more readily obtained. The general reaction is, $2\text{MO} + 2\text{S}_2\text{Cl}_2 = 2\text{MCl}_2 + \text{SO}_2 + 3\text{S}$; the appearance of sulphur, therefore, as the boat is gradually heated, is an indication of the beginning of reaction, and the temperature can be raised as gradually as desirable. Too high a temperature favours the formation of oxychloride. —J. T. D.

Iodic anhydride: Action of heat on —. M. Guichard. Bull. Soc. Chim., 1909, 5, 86—89.

IODIC anhydride, when partially decomposed by heat, acquires a brown colour, a portion of the iodine and oxygen being retained in the occluded form. The ratio between the occluded elements is the same as in the anhydride itself, and both iodine and oxygen are liberated when the brown substance is dissolved in water; but the colour is not affected by treating the compound with carbon bisulphide or fuming nitric acid. The suggestion is made that this phenomenon of occlusion, though not always apparent, may be very general in cases of thermal decomposition. —F. SONN.

Borax industry of the United States. U.S. Geol. Survey, 1908. [T.R.]

WHILE the total yield in 1907 was only 5323 tons less than in 1906, and the decrease in value only \$60,890, yet the sudden drop in market value was such that by the end of 1907 only the largest properties continued to carry on mining operations. The consumption of borax has not materially increased, and in some branches of industry it has decreased. At the same time new mines opened within the year are prepared to meet even extraordinary demands as to output. California continues to be the only State which makes a commercial production of borax annually, the few small marsh deposits in Nevada being no longer productive. In 1907 the entire output was derived from the counties of San Bernardino, Inyo, and Ventura, Cal. The output of crude borax for 1907 was 52,850 short tons, valued at \$1,121,520, as compared with 58,173 short tons, valued at \$1,182,410 in 1906.

The statistics of production of borax in California from 1900 to 1907, inclusive, are given in the following table:—

Year.	Short tons.	Value.
1900.....	25,837	\$1,013,251
1901.....	23,231	1,012,118
1902.....	20,004	2,538,614
1903.....	34,430	661,400
1904.....	45,647	698,810
1905.....	46,334	1,019,154
1906.....	58,173	1,182,410
1907.....	52,850	1,121,520

The imports of borax and borates into the United States in 1907, as compared with 1906, were as follows:—*Borax*, 1907, 2,268,065 lb., valued at \$77,258; 1906, 791,425 lb., valued at \$27,243. *Borates*, calcium and sodium (crude), and refined sodium borate, 1907, 2959 lb., valued at \$175; 1906, 57,711 lb., valued at \$2436. *Boric acid*, 1907, 534,524 lb., valued at \$23,547; 1906, 986,021 lb., valued at \$33,200.

The main feature of the borax industry since about the middle of 1907 has been the steady reduction in price, which fell from 6½c. to 7c. per lb. at New York early in the year to 4½c. and 5½c. per lb. during the latter part of the year. It was this reduction in price which caused the closing of most of the other productive mines in California, although some of them had virtually exhausted the ore of a profitable grade in their properties.

In 1907 there were five producing mines in California, one in Inyo, two in San Bernardino and two in Ventura counties. With one exception these properties had ceased production by the end of that year, though some of the operators have since commenced operations at other and more favourable places.

PATENTS.

Pyrites, pyrites cinder, and the like: Treating liquors obtained from —. J. H. Thwaites, Peterborough. Eng. Pats. 24,847, Nov. 9, 1907, and 27,506, Dec. 13, 1907.

ZINCIFEROUS materials, particularly low-grade zinc ores and tailings, are added to liquors obtained from pyrites, pyrites cinder and the like, and worked up therewith. After removal of the copper, if present, the iron may be precipitated as hydrated oxide by the addition of a suitable zinc compound. The mixture is then oxidised and subsequently peroxidised, any metal which would prevent the formation of pure white zinc compounds being precipitated at an appropriate stage of the process by the addition of a suitable sulphide (see following abstract).—C. J. G.

Metallic compounds: Separation of — by wet methods. J. H. Thwaites. Fr. Pat. 393,502, Aug. 20, 1908. Under Int. Conv., Dec. 9, 1907.

THE neutral or slightly acid solution containing compounds of several metals, is treated with zinc sulphide: (1), at the ordinary temperature whereby sulphides of silver, lead, mercury, copper, bismuth, tin, arsenic, and antimony are precipitated; (2), after heating, in order to precipitate cadmium sulphide in addition to those mentioned; or (3), first at the ordinary temperature and then after heating, in order to precipitate cadmium sulphide separately from the other sulphides. The process may also be varied in other ways. For instance, the solution may be rendered strongly acid before treatment with zinc sulphide, in which case, any arsenic or antimony present as arsenate or antimonate respectively is precipitated as sulphide, and cadmium sulphide is precipitated even at the ordinary temperature. After removing the precipitated sulphides, cobalt, nickel, and manganese may be separated from the solution by treatment with an oxidising agent. The solution may also be further treated to separate any compounds which would otherwise subsequently prevent the recovery of white zinc compounds from the solution, e.g., zinc oxide, carbonate, or hydroxide may be added, the mixture being heated and oxidised if necessary, in order to precipitate hydroxides of iron, aluminium, and chromium.—A. S.

Alkali: Apparatus for recovering —. C. F. Logan, Big Island, Va. U.S. Pat. 910,074, Jan. 19, 1909.

THE apparatus comprises a concentrating chamber in the form of a vertical stack somewhat narrower at the bottom than at the top, through which heated gases are passed in an upward direction. The liquid to be concentrated is conveyed to a trough, which surrounds the exterior of the stack at its upper end, and is thence directed on to baffles arranged in the line of travel of the heated gases after they leave the stack. From these baffles the liquid is projected against the inner walls of the stack and is finally collected in a receptacle at the bottom.—C. A. W.

Caustic alkalis: Process of making — W. T. Gibbs, Buckingham, Canada. U.S. Pat. 910,662, Jan. 26, 1909.

CAUSTIC alkalis are produced by digesting finely-divided refractory silicates containing alkalis, e.g., potash feldspar, with a solution of an alkaline-earth hydroxide, for instance, milk of lime, under steam pressure. —A. S.

Metal salts: Process of forming — W. H. Allen, Detroit, Mich. U.S. Pat. 910,982, Jan. 26, 1909.

SMELTING furnace gases containing metallic fumes are mixed with acid vapours, e.g., sulphuric acid, at a temperature above that at which combination will take place, then the temperature of the mixture is reduced below that of dissociation of the salts formed by the union of the metal and the acid, and finally the gases are treated with a spray of cold water to condense the salts. —A. S.

Boron carbide: Massive and process of making same. S. A. Tucker, New York. Eng. Pat. 22,134, Oct. 11, 1907.

VIII.—GLASS, POTTERY, AND ENAMELS.

Enamelling: Heating and pickling of the finished iron articles before — J. Grünwald. Stahl. u. Eisen, 1909, 29, 137—139.

ONLY the best brands of wrought-iron sheet should be used for enamelling. An iron of suitable composition contains 0.05—0.08 per cent. of carbon, less than 0.03 of phosphorus, 0.25—0.35 of manganese, and about 0.02 per cent. of silicon. A suitable cast-iron contains 3.5 per cent. of carbon, 2.0 of silicon, 1.4—1.8 of phosphorus, and 0.5—0.7 per cent. of manganese; for thin-walled cast-iron articles, 1—2 per cent. of good steel waste is added to the metal. The formed iron articles are heated to about 750—850° C. for not too long a period. It is important to exclude air as completely as possible during this process, to expose the surface of each article completely (i.e., not to pack the ware too tightly), and to cool slowly. Wrought-iron after this treatment should have a uniform black or velvet-brown colour. After heating, the articles are pickled for 30—45 minutes, either in hydrochloric acid (1 part of acid of sp. gr. 1.471 to 2 parts of water) at 20—30° C., or, less usually, in sulphuric

acid (15 parts of acid of sp. gr. 1.79—1.80 to 85 of water) at 70°—80° C. Both acids should be free from arsenic to avoid evolution of arseniuretted hydrogen. Pickling may be carried out in vessels provided with agitators, or through which the acid is passed systematically. As fresh acid acts very slowly, a proportion of spent liquid may be added. Spent hydrochloric acid liquors are economically reactivated by the addition of sulphuric acid. In pickling cast-iron articles, good results are obtained with sulphuric acid of 8°—10° B., to which 4 per cent. of stannous chloride or zinc chloride may be added. During heating and pickling, wrought-iron ware loses about 4 per cent. in weight, and cast-iron about 0.3 per cent. After pickling, the articles are washed in water, scrubbed, boiled in soda-lye, and finally dried at about 130° C. The sharp drying restores the mechanical properties of the iron, which are impaired by the heating and pickling. —A. G. L.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

Chimney with acid-proof lining: Tall — Engineering Record, New York, 1908, 17.—S. Proc. Inst. Civil Eng., 1908, 173, [iii], 26. [T.R.]

THE tallest chimney in America, 366 feet high, has been built at Rochester, N.Y., the height being necessary to avoid nitric acid fumes being set free at a lower elevation. These fumes have a temperature of 200° F., and their condensation would destroy concrete or ordinary brick-work, hence an acid-proof brick lining separated from the main shell by an air-space of 2 inches and supported by corbels is provided, the mortar in the lining being of a special mixture of sodium silicate and asbestos wool. This separation provides for easy relining in case of deterioration notwithstanding the precautions. A feature of the construction is the provision of perforated brick blocks in the shell, of radial form and of various sizes to suit the diminishing diameter, being 4½ inches thick and 6½ inches wide on their external faces, the lengths varying between 4 inches and 10½ inches, thus securing a strong bond. The perforations facilitate the proper burning of the brick in manufacture, and also assist the adhesive power of the mortar, this having been shown to be 61½ lb. per square inch as against 21½ lb. with ordinary blocks. The outside diameter at top and bottom is 11 feet 0¼ inch and 27 feet 10¼ inches respectively. Other dimensions, and the description of the foundations and of the protection from lightning, which is of an elaborate kind, are given. A wind-pressure of 100 miles an hour is provided against, and a maximum pressure due to this and weight, will produce an effect of 21 tons per square foot on the leeward side.

Egyptian cement trade. Board of Trade J., Feb. 4, 1909 [T.R.]

PATENTS.

Cement clinker: Process of and apparatus for making — C. Ellis, Larchmont, N.Y., Assignor to Ellis-Foste Co., New Jersey. U.S. Pat. 910,121, Jan. 19, 1909.

THE cement material is calcined in an inclined rotary kiln, from which it is delivered on to a stationary clinker in hearth in a chamber heated by a producer-gas flame

fed with hot air. Part of the combustion products from this chamber passes through the calcining kiln, and the remainder is led through regenerators for heating the air.—A. T. L.

Products for refractory, ceramic, or abrasive uses from bauxite or other aluminous earths; Process of manufacturing —. E. von Seemen, Paris. Eng. Pat. 702, Jan. 11, 1908. Under Int. Conv., Jan. 11, 1907.

X.—METALS AND METALLURGY.

γ -iron; Conditions of equilibrium between carbon monoxide, carbon dioxide, and carbon dissolved in —. F. Giolitti. Rend. Soc. Chim. di Roma, 1908, 6, 337—341.

CEMENTATION steel prepared by the usual methods suffers from the great disadvantage of non-uniform composition, the outer layers frequently being very brittle owing to the presence of free cementite. By using as cementing agent, carbon monoxide mixed with different proportions of carbon dioxide or a hydrocarbon, according to the content of carbon desired in the carburised metal, the author states that it is possible to obtain carburised zones of any desired thickness in which the carbon content (between 0.1 and 1.2 per cent.) is constant within narrow limits. This method allows of the cementation of many special steels which hitherto could not be carburised on account of the great brittleness produced so soon as the amount of carbon exceeded a certain limit. The author has studied the equilibrium: $2CO \rightleftharpoons CO_2 + C$ in presence of γ -iron (by which the carbon is dissolved) at temperatures between 850° and 1500° C. The experimental results will be published when complete, but in the meantime it is stated that results have been obtained which confirm the existence of carbides other than cementite. (See this J., 1908, 154; also Fr. Pat. 392,960 and 393,355 of 1908; this J., 1909, 25, 145).—A. S.

Cementation steel; Phenomenon of "exfoliation" in — and means for preventing it. F. Giolitti. Rend. Soc. Chim. di Roma, 1908, 6, 354—358.

A piece of soft steel has been carburised by the ordinary cementation process to a depth of from 0.5 to 3 mm., and then tempered in the usual way, there is an abrupt change of structure at a depth of from 0.2 to 2 mm. It is to this change of structure that is due the phenomenon "exfoliation" which is observed when the steel is subjected to shocks or to excessive strain. Experiments showed that the carbon content of the carburised zone does not decrease regularly from the outside inwards, and this is in accord with the fact, observed previously by the author, that when a steel in which the carbon content ranges gradually from a high hyper-eutectic to a low hypo-eutectic value (e.g., cementation steel), is cooled slowly from a higher temperature to below 900° C., liquation occurs, cementite accumulating in the hyper-eutectic zone, and ferrite in the hypo-eutectic region, with an intermediate zone in which the composition is that of the eutectic, pearlite. To prevent this liquation, and consequent "exfoliation," it is necessary only to give a period of slow cooling, and experiments in which the steel was transferred directly from the cementation chamber, without allowing it to cool therein, into the tempering liquid, confirmed this view. Another method of preventing "exfoliation" consists in carburising by the method described in the preceding abstract; in this way a carburised zone in which the carbon content rises above 0.9 per cent. may be obtained, thus avoiding the presence of free cementite.—A. S.

Cementation; Lower limit of the interval of temperature within which it is possible to effect —. F. Giolitti and F. Carnevali. Rend. Soc. Chim. di Roma, 1908, 6, 359—363.

IN A previous article (see this J., 1908, 1154), the authors have stated that cementation cannot be effected at temperatures below 700° C. This statement appears to conflict with results obtained by Charpy (this J., 1903, 631, 911) on the action of carbon monoxide on iron, but the difference is due to the interpretation of the term cementation. In the authors' opinion, the term means the carburisation of a soft steel at a temperature below its melting point, with the production of a steel which does not differ with respect to micro-structure or mechanical properties from a steel of the same composition obtained in any other way and submitted to the same thermal and mechanical treatment. A repetition of Charpy's experiments at about 600° C., showed that carbon monoxide acts upon iron at this temperature, forming a compact, adherent, grey layer, probably a carbide of iron, on the surface of the metal. It is the formation of this layer which led Charpy to conclude that cementation had taken place. Microscopic examination showed, however, that this layer has not the structure of true steel, and on removing portions of it by prolonged polishing, the structure of the steel below was found to be exactly the same as before treatment. No true cementation had therefore taken place.—A. S.

Malleable cast iron; Manufacture of —. F. Giolitti. Rend. Soc. Chim. di Roma, 1908, 6, 388—393.

THE author disputes the statements of Wüst (this J., 1908, 450) that in the production of malleable cast iron, (1), decarburisation does not take place until the carbon of the cementite has separated in the form of temper-carbon; and (2), that the oxidation of the carbon in the interior of the cast iron is due exclusively to the penetration of the heated metal by oxidising gases (oxygen, carbon dioxide). A critical examination of Wüst's results, together with the results of previous work by himself and Carnevali and Gherardi, leads him to the conclusion that besides the oxidation of temper-carbon, the carbon dissolved in the iron is also directly oxidised; and that besides the penetration of the heated metal by the oxidising gases, the migration of the dissolved carbon towards the surface of the iron, owing to differences of concentration in the inner and outer portions of the metal, also plays a part.—A. S.

Magnesium-lead alloys; Electric conductivity of —. N. Stepanow. Z. anorg. Chem., 1908, 60, 209—229. Chem. Zentr., 1909, I, 349.

THE cooling curve of magnesium-lead alloys shows a maximum, corresponding to the compound, Mg_2Pb , and two eutectic points. The formation of mixed crystals (solid solutions) could not be detected either thermometrically or by microscopic examination. In agreement with the cooling curve, the electric conductivity curve is almost a straight line between 0 and 66.6 atoms per cent. of magnesium, whilst the remaining portion consists of two separate branches. The branch corresponding to alloys with from 95.5 to 100 atoms per cent. of magnesium is of a steepness hitherto only observed with solid solutions, and the author, being of the opinion that the electric conductivity offers the most sensitive means of detecting the formation of such solutions, concludes that mixed crystals containing up to 4.5 atoms per cent. of lead are formed.—A. S.

Preparing iron for enamelling. Grünwald. See VIII.

Mineral production of British Columbia. Eng. and Min. J., Jan. 30, 1909. [T.R.]

THE following are the estimated figures for the mineral production of British Columbia, with a column showing the increase (I.) or decrease (D.) as compared with 1907:—

	1908.	changes.	
Gold, placer	\$682,000	D.	\$146,000
Gold, lode	5,291,520	I.	1,236,500
Total gold	\$5,973,520	I.	\$1,090,500
Silver	1,610,000	D.	93,825
Lead	1,654,605	D.	636,763
Copper	5,792,820	D.	2,373,724
Zinc and iron	280,000	I.	229,400
Total	\$15,219,935	D.	\$1,875,912
Coal	\$5,950,000	D.	\$350,235
Coke	1,488,000	I.	150,522
Building materials, etc.	1,200,000	I.	50,900
Total	\$8,638,000	D.	\$149,113
Summary:			
Metalliferous	\$15,219,935	D.	\$1,875,912
Non-metalliferous	8,638,000	D.	149,113
Total mineral production..	\$23,857,935	D.	\$2,025,025

PATENTS.

Iron or steel; Treatment of — for the prevention of oxidation or rust. Rudge-Whitworth, Ltd., and H. L. Heathcote, Coventry. Eng. Pat. 490, Jan. 8, 1908.

THE iron or steel articles are immersed in a mixture consisting of iron phosphate or phosphates mixed with 20 times their weight of water, to which is added 1/200 part by volume of ortho-phosphoric acid. The bath is heated and retained at the boiling point for from 30 minutes to 2 hours, in which time a greenish-black film, consisting of ferrie and ferrous phosphates, is formed on the surface of the articles. The articles are washed, quickly dried, and oiled. The coating formed is durable and highly resistant to rusting influences.—F. R.

Zinc; Separation of — from its ores or compounds. H. L. Sulman, London. Eng. Pat. 701, Jan. 11, 1908.

ZINC sulphite, which is obtained for instance by the process described in Eng. Pat. 21,672 of 1906 (this J., 1907, 1144), is roasted in horizontal revolving cylinders, from which air is excluded, and is thereby converted into zinc oxide which is practically free from sulphate or sulphide. Each cylinder is furnished with an outlet pipe to conduct away the sulphurous acid and water vapour evolved, and a few large iron balls are placed in with the charge to prevent its caking.—F. R.

Zinc; Continuous process and apparatus for the extraction of — from its sulphide. T. J. Heskett, Brunswick, Australia. Eng. Pat. 1761, Jan. 25, 1908.

THE reduction is effected by bringing the sulphide into contact with a surface of molten copper or iron. The latter is contained within a crucible or retort which is maintained at a temperature above the volatilising point of zinc either by an electric arc above the surface of the metal or by external heating. The sulphide is fed upwards through the bottom of the crucible and may, if desired, be mixed with some adhesive, such as tar, so that it does not mix with the layer of molten metal. The reduced zinc passes away at the top of the furnace to condensers, whilst the liquid sulphide of copper or iron is conveyed to a reducing chamber where the metal is recovered by subjection to an air blast and—in the case of iron—simultaneous reduction with carbonaceous matter. The reduced metal is returned by gravitation into the retort and the process repeated. The waste sulphurous gases from the reducing chamber may be used to heat the furnace, or may be mixed with the zinc vapour as it passes away to prevent the oxidation of that metal. The copper or iron, becoming saturated with foreign metals contained in the ore, has to be renewed occasionally.—C. A. W.

Furnaces; Means for charging the retorts of zinc and other analogous —. E. Dor-Delattre, Dorplein, Holland. Eng. Pat. 13,822, June 30, 1908. Under Int. Conv., July 8, 1907.

THE apparatus comprises a conveyor drum provided

with a tangential outlet, and arranged so that, by means of a screw and worm, it can be turned about its own axis. In this way, any desired inclination can be given to the tangential tube through which the material is charged into the retorts. The conveyor is formed of two discs connected by a series of propeller blades; one of these discs is fixed on the shaft of a motor, while the other contains a circular opening in its centre through which the material, fed through a hopper at the top, falls into the drum. The aforesaid blades being very shallow, their inner edges are some distance from the feeding aperture at the side, and in this way the material does not become involved in the rotation of the wheel, so as to be thrown against the walls of the casing, but falls to the bottom and is at once projected into the charging tube. The whole apparatus may be fixed to a travelling crane and, during its passage between the retorts, the supply of material can be cut off by means of a damper in the hopper.—C. A. W.

Gold; Impts. in the recovery of — by the cyanide process, and in other chemical processes wherein zinc is employed. [Zinc strips or ribbons]. E. H. Strange, C. A. Pim and F. E. Matthews, London. Eng. Pat. 7211, April 1, 1908.

MOLTEN zinc is caused to issue from a narrow orifice and to impinge at once on to a rapidly moving, and suitably cooled, disc or wheel, set horizontally or at a convenient angle, so that the zinc is received on one of its side faces, or set vertically so that the zinc is received on its periphery. The rapidly moving disc conveys away the zinc as a surface film, which immediately solidifies forming a very thin strip or ribbon, having a width similar to the cross section of the orifice. The thin strips are said to act more advantageously than the usual zinc shavings, for the precipitation of gold from cyanide solutions, or for similar chemical precipitations. If the issuing zinc comes in contact with the side of the disc, the strips will have a somewhat twisted formation, which assists in maintaining air spaces in the precipitation boxes.—F. R.

Metal coating. G. H. Clamer, Philadelphia, Pa. U.S. Pat. 909,869, Jan. 19, 1909.

IRON or other similar metal is coated with zinc and afterwards with lead saturated with that metal. The coating may also contain up to 4 per cent. by weight of tin.—C. A. W.

Compound metal body and process of producing same. J. F. Monnot, Assignor to Duplex Metals Co., New York. U.S. Pat. 909,924, Jan. 19, 1909.

ARTICLES of a light metal, such as aluminium, are brought into contact with another non-ferrous metal, *e.g.*, silver, of high melting point, the latter being in a molten condition, so that it forms a layer on the aluminium. Articles coated in this way may afterwards be soldered together.—C. A. W.

Compound metal objects; Process and apparatus for producing —. J. F. Monnot, Assignor to Duplex Metals Co., New York. U.S. Pat. 910,045, Jan. 19, 1909.

THE object to be coated is passed through a bath of molten metal maintained at a temperature much above its melting point. If desired, the object may first have been heated to any particular temperature, but the transference to the bath must be made under conditions which preclude oxidation. As the object, coated with a layer of the solidified coating metal, emerges from the bath, it is further subjected to a stream of the molten metal, so that a second layer is formed upon the first.—C. A. W.

Liquids; Apparatus for extracting — from ores or other substances. E. P. Lynch, Salt Lake City, Utah. U.S. Pat. 910,075, Jan. 19, 1909.

THE apparatus consists essentially of an endless conveyor comprising a series of connected trays, each provided with a perforated false bottom covered with a layer of filter-cloth. Each tray as it moves forward is supplied

with a thin layer of the pulp, which is uniformly distributed over the surface of the cloth, the separation of the liquid being effected by applying suction through the false bottom. Means are provided for the cleansing of the mass by the application of water over the whole surface of the filter during certain portions of its travel. The solid matter is discharged at the end of the conveyor, its complete removal being effected by a pivoted scraper which engages with the bottoms of the pans as they become inverted.—C. A. W.

Blast-furnace smelting. J. W. Nesmith, Assignor to Colorado Iron Works Co., Denver, Colo. U.S. Pat. 910,082, Jan. 19, 1909.

A MIXTURE of oxidised ores, fluxes, and a carbonaceous reducing agent is fed into a blast-furnace, which is supplied independently with air and with hot combustion gases produced by burning a suitable fuel outside the furnace.—A. S.

Blast-furnace smelting; Method of —. J. W. Nesmith, Assignor to Colorado Iron Works Co., Denver, Colo. U.S. Pat. 910,480, Jan. 19, 1909.

A MIXTURE of sulphide ores and fluxes is fed into a blast-furnace, which is supplied independently with air and with hot combustion gases produced by burning a suitable fuel outside the furnace.—A. S.

Furnace for the reduction of ores. G. F. Rendall, New York, Assignor to American Reduction Company. U.S. Pat. 910,086, Jan. 19, 1909.

THE furnace is provided internally at its upper portion with an air chamber, and, at its lower portion, with a water jacket. Beneath the latter, a second chamber of annular shape is arranged so as to communicate with the air chamber. Means are provided immediately above the hearth for the introduction of a reducing gas, and, by the discharge of an injector into a condenser connected with the top of the furnace, for the creation of a suction above the charge. The hearth is supported on a carriage and can be raised or lowered at will.—C. A. W.

Crucible furnace; Gas generating —. E. H. Schwartz, Assignor to Kroeschell Bros. Co., Chicago, Ill. U.S. Pat. 910,091, Jan. 19, 1909.

THE combustion chamber is surrounded by a supplemental chamber, tuyères being arranged so as to communicate between the two. Means are provided for introducing fluid tangentially into the supplemental vessel and also for removing any accumulated liquid from the latter without the admission of air or escape of fluid.—C. A. W.

[*Electrical*] *Air propelling and ozonising apparatus.* J. R. Craig, jun., London. Eng. Pat. 585, Jan. 10, 1908.

THE spindle of an electric fan is connected with a high or low tension magneto-apparatus, or the fan motor may be provided with windings after the manner of a rotary converter; in either case the induced low tension current is transformed by a suitable induction coil. The secondary of the latter is connected to one or more open electrodes, consisting of radial spring wires mounted on the fan spindle on each side of a disc of mica, and located between the fan blades and the motor.—B. N.

Furnaces; Electric —. A. H. Imbert. Eng. Pat. 17,281, Aug. 17, 1908.

THE furnace comprises a cylindrical drum, a, closed at the ends by plates, b, provided with circular openings, c.

and lined with refractory material, *d*, the whole being revolved by wheels, *c*, operating in tracks, *a*¹. The central portions, *g*, of the ends, consist of refractory material, forming stationary hubs through which the electrodes pass, the hubs being provided with embedded pipes, *h*, for the circulation of a cooling fluid. The hubs, *g*, are slightly smaller in diameter than the orifices, *c*, and the gases escape from the furnace through the annular spaces, *l*, an annular box, *m*, covering each space and serving to collect and direct the gases into the pipes, *n*. Each end wall of the rotatable part is provided with two or more apertures, *o*, the charging openings on one side being arranged directly opposite to those on the other, which serve as discharging apertures. Openings, *r*, for observing the position of the arc, are arranged in the middle portion of the drum, and the length and diameter of the latter are so proportioned that the material will be directly under the arc during the treatment.—B. N.

Furnaces: Electric —. The British Thomson-Houston Co., Ltd., London. From the General Electric Co., Schenectady, N.Y. Eng. Pat. 23,071, Oct. 29, 1908.

A TUBE of fused alumina is wound with a spiral ribbon of a refractory metal, such as platinum, acting as the heating conductor, a packing of alumina in an earthenware tube surrounding the heating conductor and alumina tube, and this in turn being surrounded by a packing of asbestos fibre in an earthenware pot. For the production of lamp filaments of tungsten, the alumina tube is placed in a vertical position, and one end is connected to a water-cooled iron tube serving as a cooling chamber, hydrogen gas being passed through the alumina tube and cooling chamber. For general use, or for dental work, a similar form of furnace is described, with a muffle-shaped tube of alumina.—B. N.

Batteries: Reversible galvanic —. H. C. Hubbell, East Orange, N.J., and H. W. Fuller, New York. Eng. Pat. 17,331, Aug. 18, 1908.

THE active material of the positive plate consists of a mixture of 60 per cent. of nickel hydroxide and 40 per cent. of silver oxide, compressed into a block on each side of a perforated supporting plate, and secured in position by envelopes of "asbestos filter papers," covered by wire cloth pockets, the edges of the latter being fastened by metal binding strips. The negative plate consists of dry-pressed tablets of cadmium oxide and nickel hydroxide, similarly mounted. Sodium or potassium hydroxide is used as the electrolyte.—B. N.

Acetates and in particular acetate of soda: Electrochemical process for the manufacture of —. C. H. Jacob, Lyon, France. Eng. Pat. 726, Jan. 11, 1908.

Electric steel furnaces: Characteristics of — in relation to decarboxation and desulphurisation. R. Amberg. Stahl u. Eisen, 1908, 29, 176—178.

THE removal of sulphur in the various types of electric furnace is explainable by reference to already ascertained facts. The main characteristic of the electric furnace is its very high temperature; and the mechanical and chemical results of this enter into the question. The

highest temperature is obtained in the Héroult furnace, just under the electrodes: this local high temperature is transmitted through the slag to the metal, and the local differences of temperature are sufficient to set up considerable convection currents. In the Stassano furnace the centre is, for a similar reason, hotter than the sides, but the differences seem not to be enough to effect mixture of the contents, as the bath is rotated at intervals round an inclined axis. In the induction furnace the temperature all through a vertical section is approximately the same: motion, and hence mixture, is obtained by alteration from place to place of the section of the bath, and (in the Röchling-Rodenhauser furnace) by means of secondary electrodes. There is also in the induction furnace an electrodynamic rotation of the contents of the bath. The temperature is nowhere so high as in the hottest parts of the Héroult furnace, and the metal is hotter than the slag. The chemical results of the high temperature in electric furnaces are, first, the direct increase of reaction-speed, and second, the higher fluidity of metal and slag, facilitating interchange of constituents and hence reaction, both in each (homogeneous) and between the two (heterogeneous). Homogeneous reaction in the slag will occur much more readily in the Héroult than in the induction furnace, as the temperature is so much higher; and those heterogeneous reactions will occur most readily in the induction furnace by which heat is carried to the slag. Hence the desulphurisation by calcium carbide, added or generated in the Héroult furnace, is not practicable at the lower temperature of the induction furnace; but the reaction is effected by ferrosilicon, for both the high temperature generated by the oxidation of the ferrosilicon, and the silica produced, render the slag more fluid and facilitate reaction. The removal of sulphur, whether by calcium carbide or by ferrosilicon, depends ultimately on the formation of calcium sulphide, and is facilitated by a reducing atmosphere (in which respect the Héroult furnace has the advantage over the induction furnace); though the segregation of manganous sulphide at the surface of the metal bath perhaps plays a subsidiary part. The formation of silicon sulphide, suggested by Osann, should not be left out of consideration, either; in an experiment of the author's on the behaviour of ferrous sulphide and silica in the electric arc, a quantity of silica was evolved far too great to be accounted for by simple volatilisation, and in all probability silicon sulphide was here formed, volatilised, and burnt to silica and sulphur dioxide. (See also this J., 1908, 691, 757, 817, 1071.)—J. T. D.

Copper sulphate: Electrolysis of solutions of —. F. Foerster. Z. Elektrochem., 1909, 15, 73—76.

THE author replies to Meyer's criticisms of his work and theories (this J., 1908, 863). He considers that the formation of cuprous sulphate at the cathode is due to the action of the current, according to the reaction $\text{Cu}'' + \ominus \rightarrow \text{Cu}'$, which takes place more readily than does the deposition of metallic copper until the equilibrium indicated by the equation, $2 \text{Cu}' : \text{Cu}'' + \text{Cu}$, is reached, i.e., until the solution is saturated with cuprous sulphate at the temperature of the experiment. The fact that the amount of cuprous oxide deposited by the current at low potentials is much less than the theoretical is due to the hydrolytic dissociation of cuprous sulphate into cuprous oxide and sulphuric acid, and to the reverse reaction, according to which cuprous oxide cannot be separated from the solution as soon as the latter has attained a certain degree of acidity.—A. G. L.

PATENTS.

Copper: Electrolytical refining of —. J. Awalo. St. Petersburg. Eng. Pat. 26,829, Dec. 4, 1907.

CRUDE copper is used as the anode, the electrolyte consisting of a neutral or alkaline solution of a cupric salt, protected from the air by a layer of oil. The cuprous salt may be produced by electrolysis, or by the previous action of metallic copper upon a cupric compound.—B.

Detinned material; Apparatus for washing — after or before electrolysis. The London Electron Works Co., Ltd., and E. Kardos, London. Eng. Pat. 17,113, Aug. 14, 1908.

A RING or carrier, provided with a toothed wheel, is mounted upon ball bearings on the washing tank, so that, by means of a pinion, the ring may be made to rotate alternately to the right and left. The perforated rectangular cage, containing the material, is lowered into the tank, and by means of a bar attached to the cage which engages with stops on the ring, the rotation of the latter may be imparted to the cage. The liquid from the washing tank passes into a settling tank, of sufficient area to allow of the separation of any suspended solids. The cleared liquid flows over a partition or bay into a receiver, from which it is pumped up again into the washing tank.—B. N.

Steel; Refining — in electric furnaces. Bismarckhütte, Upper Silesia. Eng. Pat. 6029, March 18, 1908. Under Int. Conv., Sept. 16, 1907.

SEE Fr. Pat. 386,786 of 1908; this J., 1908, 814.—T. F. B.

XII.—FATTY OILS, FATS, WAXES, AND SOAPS.

Olive oils giving Baudouin's reaction; Tests of the purity of —. A. Zega and K. N. Todorovic. Chem.-Zeit., 1909, 33, 103.

A METHOD was found by the authors based on the behaviour of the hydrochloric acid solution of the red colouring matter described in this J., 1894, 69, on dilution with water. The oil under examination was examined by Villavecchia and de Fabris' well-known method of applying the Baudouin test. The mixture was shaken in a small separating funnel, and 5 c.c. of the hydrochloric acid layer withdrawn, diluted with water to 25 c.c. in a graduated cylinder, which was then shaken and allowed to stand. In the case of these pure olive oils, the colour disappeared within 5 to 8 minutes, whereas in the case of an oil containing 3 per cent. of sesamé oil, it persisted for 30 minutes.—C. A. M.

Carbon tetrachloride; Use of — in the quantitative determination of fat. O. Rammstedt. Chem.-Zeit., 1909, 33, 93—94.

THE author's experiments, described in detail, show that in the extraction of seeds a higher extract is obtained by the use of carbon tetrachloride than with ether. For example, a sample of linseed meal yielded 9.39 per cent. of extract to ether in 5 hours, as compared with 10.62 per cent. in 2½ hours, and 11.35 per cent. in 3½ hours to carbon tetrachloride. This is attributed to the extraction of more non-fatty substances by the latter solvent, and since it is also more difficult to expel carbon tetrachloride than ether from the extracted residue, the author considers that carbon tetrachloride should not be used as an extraction-solvent in analytical work.—C. A. M.

Chinese vegetable tallow. Ch. of Comm. J., Feb., 1909. [T.R.]

DURING recent years the imports of Chinese vegetable tallow to Europe, from China, have very largely increased, as is indicated by the figures in the following table of the exports from China to the United Kingdom,

Exports of vegetable tallow from China.

Country to which exported.	1905.		1906.		1907.	
	Quantity.	Value.	Quantity.	Value.	Quantity.	Value.
	lb.	£	lb.	£	lb.	£
United Kingdom	983,600	22,609	2,828,130	63,906	8,202,665	218,403
France	1,847,200	42,480	2,781,600	62,865	5,322,930	142,462
Italy	3,667,200	83,127	4,651,065	104,901	3,579,200	95,482

France, and Italy, taken from the returns of the Chinese Imperial Maritime Customs. Nine-tenths of the exports of vegetable tallow from China come from Hankow.

PATENTS.

Soap; Apparatus for making —. A. H. Trit-hard, Toronto. U.S. Pat. 910,083, Jan. 19, 1909.

THE apparatus consists of an oblong vessel with rounded ends, in which two annular heating devices ("headers") are mounted, side by side, a certain distance above the bottom. Connections are provided for supplying steam to the "headers," and steam heating pipes extend upwards from the "headers" so as to form vertical passages for the soap material. Between the "headers," at the bottom of the vessel, are agitators composed of a series of longitudinal parallel slats, connected together at an angle to the horizontal, and capable of being moved to and from the sides of the vessel, so as to convey soap material towards the vertical passages. A shaft is mounted centrally in each vertical passage and carries, at the bottom, a rotary scraper; and above this, a lifting screw for the purpose of raising soap material through the passages.—A. S.

Glycerin; Process of distilling —. F. J. Wood, New York. Assignor to Marx and Rawolle, New York. U.S. Pat. 910,440, Jan. 19, 1909.

IN the process claimed, part of the steam from which the glycerin vapours of a previous distillation have been condensed, is returned to the still, whilst the remainder is condensed, and subsequently evaporated by means of the heat given off by the glycerin in its condensation. Live steam is also introduced into the circuit between the still and the glycerin condenser.—C. A. M.

Fatty matters; Apparatus for extracting — on a large scale by means of carbon tetrachloride. P. Bernard. Fr. Pat. 394,314, Nov. 22, 1907.

SEE Eng. Pat. 28,364 of 1907; this J., 1908, 578.—T. F. B.

XIII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, &c.

(A).—PIGMENTS, PAINTS.

Oil paintings; Formation of cracks in —. E. Täuber. Chem.-Zeit., 1909, 33, 85—86, 94—95.

IN the author's comparative experiments to determine the influence of different pigments upon the cracking of paintings, 42 oil colours were tried. Successive layers of these were painted upon the ordinary prepared canvas at similar irregular intervals, the third and last being given six months after the first. The formation of cracks varied considerably, even when the pigments were used in one and the same medium, the so-called "quick-driers" being superior in this respect to the slowly drying pigments. The nature of the surface of the half-dry layer (*i.e.*, whether bright or dull) had no influence upon the results. The most pronounced and most numerous cracks were formed in pigments laid upon a grounding of red-lead, and the nature of the surface (whether glass, iron, aluminium, or sized paper) had no influence upon the cracking. Only very absorbent surfaces, such as are unsuitable for oil painting, diminished this tendency. Zinc white, white lead, and the two cobalt greens used as ground pigments formed layers particularly liable to crack. Zinc white also proved dangerous as a surface pigment, though the other three were innocuous. Surface coats of red lead never cracked, but cracks frequently appeared with the following pigments:—Chrome yellow, the two cobalt blues, alizarin

orange, carmine, light ochre (raw and burnt), blue-green oxide, green earth, Naples yellow, and dark cadmium yellow. In practice the ground coating ought to be

allowed to dry thoroughly before the next coating is applied in a thin layer. The addition of various resins to the drying oil had no effect in preventing cracks, but solutions of resins, such as Zanzibar copal and gum dammar resin, in turpentine oil, mixed with the pigments without oil, gave layers which showed no signs of cracking after a year. It is suggested that a mixture of a solution of a resin in turpentine oil with yolk of egg might form a sufficiently elastic medium which would closely resemble the drying oils in optical properties and would prevent the formation of cracks. An addition of egg-yolk to poppy oil, however, did not prevent the injurious influence of the latter. In special experiments with different oils it was found that poppy oil had the greatest effect in promoting the formation of cracks, then nut oil, and then linseed oil. Of 400 surfaces coated with poppy oil colours, 83 showed cracks, whilst 65 of the same number of surfaces coated with nut-oil colours cracked, but only five of those of the linseed oil experiments. The pigments in these experiments were red lead and zinc white. It would seem advisable, therefore, to discontinue the use of poppy oil in favour of linseed oil, wherever practicable. If the formation of cracks is due to the oxidation process being accompanied by a movement of the lower layer of paint, one would anticipate a simultaneous cracking of the lower layer, but in the author's experiments this was never found to be the case, the lower layer being always intact. A more likely explanation is that by the interaction of certain pigments under suitable conditions, electrical currents are produced, which cause a state of tension in the still moist surface layer. This is supported by the fact that in many cases disruption occurs while the upper coating is still soft and "tacky." The probability of the influence of electric currents on the drying process is shown by the fact that coats of the same paint spread in layers of equal thickness upon different non-absorptive surfaces require very different lengths of time to dry under parallel conditions. Thus zinc white in poppy oil spread in a moderately thick layer on copper dried in 9 days, on lead in 18 days, on porcelain in 6 months, and on zinc in a year. Taking porcelain as a neutral ground it would seem that copper has an accelerating and zinc a retarding influence on the drying of zinc white paint.—C. A. M.

PATENT.

Colouring matter suitable for use as a pigment or lake; Manufacture and production of a —. J. Y. Johnson, London. From Badische Anilin und Soda Fabrik, Ludwigshafen on Rhine, Germany. Eng. Pat. 23,714, Dec. 9, 1908.

By treating 3-chloro-6-nitraniline with formaldehyde, a greenish-yellow colouring matter can be obtained which is suitable for use as a pigment, or lake. *Example:*—345 parts of a 10 per cent. paste of 3-chloro-6-nitraniline and 30 parts of a 30 per cent. solution of formaldehyde are heated together, in a closed vessel, at a temperature of 70°–80° C., and with stirring, until no diazotisable base remains. The mixture is then allowed to cool and the product is filtered off and washed.—P. F. C.

(B.)—RESINS, VARNISHES.

PATENTS.

Varnishing, impregnating, and insulating materials; New bodies applicable as — and process for their manufacture. G. G. Diesser. Fr. Pat. 393,948, July 29, 1908. Under Int. Conv., April 24, 1908.

The bodies are prepared by heating fatty or resin acids or their compounds, or substances containing the fatty or resin acids or compounds, with carbohydrates such as starch or cellulose (oxycellulose, hydrocellulose), or with amino-acids or their compounds, or substances containing these acids or compounds, or with mixtures of these materials. The heating may be carried on: (a), with or without pressure; (b), in an inert atmosphere; (c), with escape of volatile products of decomposition; (d), at temperatures exceeding that at which the reacting substances decompose.—L. E.

Shellac preparations; Manufacture of durable —. F. Daum. Ger. Pat. 206,144, May 22, 1907.

THE moist shellac obtained by precipitation with acid from alkaline solution, is converted into a viscous solution by means of the smallest possible quantity of an indifferent solvent or of borax solution, and the solution is evaporated. For instance, 100 kilos. of the moist shellac are dissolved by means of 30 kilos. of borax and 30 kilos. of water. The solution is then heated until a portion is found to set in a few minutes to a hard transparent product when placed on a glass plate.—A. S.

Copals; Treatment of hard and semi-hard — and the preparation of varnishes. H. Terrisse, Geneva. Eng. Pat. 23,039, Oct. 29, 1908. Under Int. Conv., Oct. 29, 1907.

(C.)—INDIA-RUBBER, &c.

Rubber; Manihot — from German E. African plantations. W. Schellmann. Der Pflanzer, 1908, [3]; Gummi-Zeit., 1909, 23, 561.

THE author has examined a large number of samples of rubber obtained from *Manihot* trees (1), of different ages, and (2), grown in different localities, with the object of ascertaining whether there is any corresponding difference to be traced in the composition of the raw rubber. The results obtained show that any differences are only small, and consist mainly of a slight decrease in the amount of resin in the rubber from the older trees.

In the results yielded by rubbers obtained from trees, of approximately the same age, grown in different districts, the differences are much of the same order, the resin-content varying from as low a value as 5.56 per cent. to 11.73 per cent. in the case of two 3 year old trees. —E. W. L.

PATENTS.

Rubber; Treatment or preparation of —. F. R. Durham, London. Eng. Pat. 5868, March 16, 1908.

IN order to dispense with the usual vacuum drying apparatus, the rubber, after coagulation, is passed between macerating rollers and then through a "creeping" machine and a sheeting machine having rollers heated to 100° to 120° F., by which means the rubber is softened and the water sufficiently removed to permit the sheets to be made into blocks. Provision is also made for heating the macerating rollers.—R. L.

Indiarubber; Treatment of —. T. Cockerill, Colombo, Ceylon. Eng. Pat. 21,441, Oct. 10, 1908. Under Int. Conv., Oct. 12, 1907.

THE caoutchouc is separated from the latex by means of an electric current, whilst on or in contact with a travelling anode. In a special form of apparatus claimed for this purpose, the anode consists of an endless travelling belt, the upper surface of which is made electrically active by contact with a brush connected with the positive pole of a dynamo, &c. Above this, at a distance of, say, $\frac{1}{4}$ to $\frac{1}{2}$ inch, is fixed the cathode, which is connected with the negative pole of the dynamo. The latex falls from a trough through a tilter, and is delivered in a regulated quantity on to the surface of the travelling anode, which is provided with raised portions at the edges so as to form a sort of trough. The belt travels forward very slowly, and under the action of the current becomes coated with a sheet of caoutchouc. At a certain

point this is removed by means of scrapers and guided by means of rollers into a washing tank of hot water, where it is scrubbed with revolving brushes or the like. Thence it is conveyed between rollers internally heated, and, if necessary, dried by other means before being delivered on to a table where it is cut into smaller sheets. The spent latex falls into a tank below the travelling belt, and, if it still contains caoutchouc, is again treated in the same way. Advantages claimed for this process are speed and the production of a purer rubber, which keeps well, retains its elasticity, and shows no signs of stickiness after a long time.—C. A. M.

Caoutchouc; Method of manufacturing solutions of —. E. Fischer, Schöneberg, Assignor to Siemens und Halske A.-G., Berlin. U.S. Pat. 910,520, Jan. 26, 1909.

XIV.—TANNING, LEATHER, GLUE, SIZE.

Gambier; A new sort of —. J. Paessler. Collegium, 1909, 16—20, 21—22.

A FACTORY in Indragiri (Sumatra) is now making a new form of gambier, under similar conditions to those in vogue for the manufacture of tanning extracts, *viz.*, by extraction of the twigs and leaves of the gambier shrub with water, and concentration of the extract by evaporation in vacuum pans. By this method a much better product is obtained than by the crude method in use for the manufacture of ordinary cube and block gambier. Experiments with this new form ("Indragiri gambier") show it to contain about 3 per cent. more tannin than block gambier and much less water and insoluble matter. The extract dissolves almost clear, and yields a good leather, much superior in colour to that obtained by the use of ordinary gambier. Liquors of 8, 20, 40, and 60 grms. of gambier per 250 c.c., yielded on analysis almost identical relative percentages of tannin and non-tannins, showing that the material contains no difficultly soluble tannin, and therefore in practice no waste will occur by the use of strong liquors.—H. BR.

Willow bark; Valuation of — by Von Schroeder's hydrometer method. W. Appellius and F. Merkel. Collegium, 1909, 22—24.

WILLOW bark is an excellent tanning material and is used extensively in the Russian leather industry, both for the manufacture of light and heavy leather. With a view to obtaining a quick method for the valuation of the bark, experiments have been made with Von Schroeder's hydrometer method. The method gives very similar results for tannin to those obtained by analysis, and is an admirable check for the buyer who cannot have every parcel of bark analysed.—H. BR.

Colour values [of tanning materials]; Determination of —. G. A. Kerr. J. Amer. Leather Chem. Assoc., 1909, 4, 1—9.

THE determination of the colour value of tanning materials is discussed. The writer experienced difficulty in obtaining really comparative results with the pelt test with sheep skin, the leather produced even with the same tanning material varying in colour with the texture and thickness of the skin. A few experiments were made with cotton cloth (see Reed, this J., 1909, 101) which apparently possesses the advantages of uniform texture and quality and the absence of any need for special preparation before use, but which is scarcely likely to appeal to the leather manufacturer. The author considers that all these methods leave the practical results to the imagination. The Lovibond tintometer is also found to give widely discordant results, but it is suggested that this might be remedied to some extent if more attention were paid to securing a uniform method for illuminating, and if the observations were carried out in a special dark room. The author suggests the use of the photometer for ascertaining the colour density of a tanning infusion and is endeavouring to devise a suitable instrument.—H. G. B.

Sole leather; The quality of —. R. A. Earp. Leather, 1909, 1, 7—10.

THE author discusses the causes of the superiority of the old-fashioned sole leather tanned in weak liquors over that tanned by modern processes. This he ascribes to the greater proportion of soluble non-tannins absorbed in modern sole leather tanning, which increased proportion is due to the greater concentration of the liquors and to the development of a greater absorptive power for non-tannins by the hide. The readiness with which drum-tanned sole leather wets back in water is considered to be due to the reversible absorption of these soluble non-tannins.—H. G. B.

Tanning and adsorption compounds of gelatin. Lüppler-Cramer. Z. Chem. Ind. Kolloide, 1909, 4, 21—23.

COLLOIDAL vanadium oxide is a powerful tanning agent: a one per cent. solution of vanadium chloride immediately coagulates a ten per cent. gelatin solution, whilst it renders sheets of gelatin insoluble in boiling water: as in the case of ferric chloride, etc., the vanadium chloride can be eliminated by means of potassium oxalate solution; in other respects the compound formed is analogous to the adsorption compounds of the salts of iron, chromium, and aluminium with gelatin. Albumin is immediately coagulated and gum arabic rendered insoluble by means of vanadium chloride solution. Nickel and cobalt salts do not tan gelatin, but their colloidal oxides possess strong tanning properties: the colloidal sulphides of nickel and cobalt also coagulate gelatin solutions. "Basic" chrome alum is a very powerful tanning agent; a wet photographic plate bathed for a short time in its solutions, and deprived of the superfluous moisture, can be dried over a flame without melting the film. The tendency of the compounds of higher oxides of metals to form adsorption compounds may be attributed to the fact that they more readily undergo hydrolytic dissociation, and the resulting oxides, in the form of hydrosols, are very stable.—T. F. B.

PATENTS.

Degreasing hides, skins, etc., and apparatus for extraction with volatile substances. H. A. Deroy. Fr. Pat. 394,201, Sept. 11, 1908.

THE extraction of grease, etc., from skins is effected in a series of communicating vessels, in which the skins are suspended, and which are connected to a suction device. A vacuum is first produced in the vessels in order to remove air and moisture from the skins, and the extraction is then performed in the usual way with a volatile solvent. In order to remove the last portions of the solvent from the skins, steam at a low temperature is admitted, and is subsequently condensed to recover the solvent. The skins are dried by increasing the vacuum and admitting dry steam at a relatively low temperature.—A. S.

Tanning extracts; Process for increasing the solubility of, and decolorising —. A. Kumpfmiller. Fr. Pat. 394,340, Sept. 16, 1908. Under Int. Conv., Sept. 28, 1907.

WASTE sulphite cellulose lyes which have been freed from sulphurous acid and lime, and then concentrated, are mixed with tanning extracts, in order to render them more soluble and to partially decolorise them, as well as to increase their content of "filling" substances, *i.e.*, substances which impart "body" to the leather. The process is specially applicable to strongly coloured extracts, such as mangrove extracts. It is stated that a mixture of the concentrated sulphite lye and quebracho extract has similar tanning properties to oak bark.—A. S.

Colloidal organic substances; Process for the treatment of —. The Arabel Manufacturing Co. Fr. Pat. 394,173, Aug. 28, 1908.

THE object of this process is to prevent the coagulation of colloidal organic substances at ordinary temperatures. The colloid (*e.g.*, gelatin, glue, agar-agar, casein, starch,

commercial dextrin) is treated with a solution of a salt of an organic sulphonic acid or derivative. Thus, if 300 parts of dry skim- or lude-glic are dissolved at 65–70° C. in a solution consisting of 400 parts of water and 80 parts of sodium naphthalenesulphonate, a mixture is obtained which remains liquid on cooling; the dried and ground mixture readily dissolves in warm water and even in dilute alcohol to a solution which remains liquid as before.—L. E.

Hides; Process of preparing:— for the manufacture of leather. E. Leconte, Estaires, France. Eng. Pat. 22,368, Oct. 21, 1908.

XV.—MANURES, &c.

Soils; Action of heat and antiseptics on —. S. U. Pickering. J. Agric. Sci., 1908, 3, 32–54.

IN a previous paper (this J., 1908, 867), the author showed that when soils are heated, their content of soluble organic matters is increased, and that the soils become more favourable to vegetation but less favourable to germination. He has now found that treatment of the soil with volatile antiseptics produces an effect similar in all respects to that of heat. In various experiments recorded, soils were treated in the proportion of 1 kilo. of soil to 10–20 c.c. of antiseptics, such as carbon bisulphide, ether, chloroform, and benzene. The different antiseptics differ slightly in the intensity of their action, carbon bisulphide being the most active and ether the least, but the inhibitory substance formed by each, if not identical with that produced by heating, is exactly similar as regards the various effects it produces. The parallelism is so close that it is possible to calculate, for each antiseptic, the temperature at which heating produces an equivalent effect, and the same result is arrived at whether this calculation be based on the increase of soluble organic matter, the stimulation of vegetable growth, or the restriction of germination of seeds. The temperature equivalents of the action of the various antiseptics range from 60° to 75° C. When the treated soils are kept for a few weeks at a summer temperature, some of the organic matter which had been rendered soluble reverts to the insoluble condition, and the inhibitory action is reduced; the same reversion takes place in heated soils, especially in presence of water; in ordinary soils the soluble organic matter increases under similar conditions. The author is of opinion that all these changes are probably to be explained in chemical terms, and that they are not dependent on changes brought about in the bacterial flora of the soil. The co-existence of two opposite changes in heated soils complicates the question, but it would appear that at temperatures above 125° C. the changes due to heating are of a different order and do not produce the effects above described. All soils appear to respond to the action of heat; the proportion of the inhibitory substance formed depends on the increase in the amount of organic matter rendered soluble by the heating, but the total quantity of soluble organic matter is not always a measure of the inhibitory action of the heated soil. There appears to be no connection between the fertility of a soil and the extent to which it is altered by heating. Soils in their natural state appear to contain a certain amount of this inhibitory substance, as they act less favourably towards germination than pure water. The richer soils and those containing most soluble organic matter are slightly less favourable to germination than poorer soils.—J. F. B.

XVI.—SUGAR, STARCH, GUM, &c.

[*Sugar*] *Diffusion process; Scalding —.* K. Kaiser. Deutsche Zuckerind., 1909, 34, 97–102.

THIS process consists in heating the fresh slices with steam in the diffuser before introducing the juice. Earlier attempts to utilise this process proved unsatisfactory, but the author has used it with success during the past two campaigns. In one factory in which the process was used, the battery consisted of twelve diffusers, seven of these being under pressure. Diffusion waste water, mixed with the liquor expressed from the exhausted slices, was used alternately with fresh water, to supply the battery. The steam was obtained from the second effect at a temperature of 90–93° C., this temperature being reduced to about 75° C. in the diffuser. The process is preferable to that of ordinary diffusion on several grounds. The juice extracts more sugar from the fresh slices, the battery works more smoothly, and diffusion is more rapid. Dilution of the juice, owing to condensation of the steam, does not take place to any appreciable extent. The juice drawn off is more easily worked up than that obtained by ordinary diffusion, and the exhausted slices appear to furnish a better cattle food.—L. E.

Lactose; Methods of determining the purity of — as given in different pharmacopaeias. Hillringhaus and Heilmann. Chem.-Zeit., 1909, 33, 86.

THE German Pharmacopoeia prescribes that when 15 grms. of lactose are shaken at intervals for 30 minutes with dilute alcohol, and the liquid filtered, 10 c.c. of the filtrate should not become turbid when mixed with an equal volume of absolute alcohol, and on evaporation should not leave a residue weighing more than 0.01 gm. The authors' experiments show that the temperature has a great influence on the results of this test. Thus at 16° C. four samples of commercial lactose and one of pure lactose gave results in accordance with the official requirements; at 20° C. one of the samples yielded 1 mgrm. too much residue; and at 28° C. even chemically pure lactose gave 10 mgrms. too much. In the Japanese Pharmacopoeia an additional test is given:—1 gm. of the lactose when mixed with 5 c.c. of sulphuric acid in a shallow basin should only show a slight coloration after an hour at a temperature not exceeding 15° C. According to the authors it is essential not to let the temperature exceed this maximum, but the results are fairly similar with different strengths of acid not below 92 per cent. The form of the basin has considerable influence (the wider the surface the less the coloration), but it makes but little difference whether the basin be exposed to the air or not. Adulteration of lactose with as little as 0.1 per cent. of sucrose is readily detected by this test, the carbonised sucrose appearing as small black points upon a white ground. In the authors' opinion both the above-mentioned tests have been the cause of incorrect conclusions, and the conditions under which they are to be made ought to be more accurately defined.—C. A. M.

PATENTS.

Sugar juice; Process for evaporation of — with a view to manufacture of crystallised sugar. P. Lagrange and J. F. P. Kestner. Fr. Pat. 394,493, Sept. 22, 1908. Under Int. Conv., Oct. 9, 1907.

AN earlier process described in Fr. Pat. 324,777 of 1902 (this J., 1903, 643) necessitates evaporation in two stages and addition of sugar to the syrup. These disadvantages are removed in the present process which depends on the fact that sugar juice may be concentrated under ordinary pressure to such a degree that its boiling point exceeds 120° C. without appreciable decomposition, provided that the operation is not too long continued. The juice from the ordinary evaporators, or, in refineries, the juice which is ready to boil to grain, is transferred to an evaporating apparatus and preferably to a circulation evaporating apparatus such as that described in Fr. Pat. 315,973 of 1901, or in Fr. Pat. 361,524 of 1905 (this J., 1906, 874).

Here it is heated under atmospheric or higher pressure in order to obtain, on cooling in a crystallising vessel, all or nearly all the crystallisable sugar.—L. E.

Diffusion juices of high density ; Process for the treatment of — by the preliminary action of gaseous sulphurous acid. M. E. R. J. M. Lambert. Fr. Pat. 394,577, Sept. 23, 1908.

The object of this process is to precipitate coagulable matter from diffusion juice of high density in order to facilitate the working up of the latter. Precipitation is effected by treating the juice, heated to at least 85° C., with sulphur dioxide in one compartment of a reservoir, from whence the juice overflows into a second compartment, and runs thence by a pipe into a tank where it is defecated with lime. Contact between the juice and the sulphurous acid is so short, that in spite of the high temperature of 85° C., no inversion of sugar occurs. A float in the sulphiting compartment controls a valve which governs the supply of air to the sulphur furnace, and the amount of sulphur dioxide produced is thereby regulated according to requirements.—L. E.

Starch ; Process for the treatment of —. The Arabol Manufacturing Co. Fr. Pat. 394,167, Aug. 27, 1908.

AN earlier process (this J., 1907, 478) in which a mixture of starch and a hydrocarbon was treated with caustic alkali, involved the subsequent neutralisation of the product. In the process now described, the starch is rendered capable of swelling in cold water by treatment with a thiocyanate, the latter being subsequently removed by washing. Thus, 100 parts of dry, powdered potato starch are intimately mixed with 80 parts of a 50 per cent. solution of ammonium thiocyanate in water to which 40 parts of alcohol have been added. A small quantity of sodium sulphite may be added to prevent discoloration due to traces of iron which may be present. The thiocyanate is then removed by washing with alcohol or acetone, etc. The product swells in cold water to a paste which appears to possess, at ordinary temperatures, all the properties of starch gelatinised at higher temperatures.—L. E.

Colloidal substances. Fr. Pat. 394,173. See XIV.

XVII.—BREWING, WINES, SPIRITS, &c.

Husked barleys ; Losses in the steeping of —. M. Rigaud. Z. ges. Brauw., 1909, 32, 41—42.

THE normal loss suffered by barley in the steeping process is very small (0.6—1.5 per cent.), and A. J. Brown (this J., 1908, 134) explained this circumstance by showing that the testa of the corn constitutes a semipermeable membrane through which the soluble constituents of the corn cannot penetrate outwards. It occurred to the author that a mechanical husking treatment might involve such a serious injury to the testa that its protective action would be destroyed, and considerable losses might take place in the steep waters. The author has examined several samples of barley from which the husk had been removed ; he steeped the corns first in a 1 per cent. solution of copper sulphate, washed them, and then transferred them to a 1 per cent. solution of potassium ferrocyanide. The corns were thus stained red at those points where the testa had been broken. It was found that the number of damaged corns depended on the severity of the husking process, and that, with a husking-loss of 1.34 per cent., the percentage of damaged corns was only increased by 2, whereas with a husking-loss of 2.08 per cent., the number of damaged corns was increased by 70 per cent. When the steeping-losses were determined, it was found that the corns showing a husking-loss of 1.34 per cent. lost 0.58 per cent. of soluble matters in the steep, as against 0.44 per cent. before husking. Hence it is concluded that the husking process, if properly carried out, involves no serious loss of barley substance during steeping. But the result of the husking does not depend only on the quantity of the husk substance removed ; it depends also on the uniformity of its removal and the extent of the

damage done to the testa. But even when the husking was with intention roughly conducted, the steeping-loss was only increased from 0.54 per cent. before husking to 1.05 per cent. after husking.—J. F. B.

Malt extract ; Increased yield of — by previous doughing of the grist. C. Bleisch. Z. ges. Brauw., 1909, 32, 43—44.

IN a previous note (this J., 1909, 34) the author made some observations on var Hest's investigations on this subject. It would appear that when the doughing is effected at temperatures below 25° C., there is a slight increase in the yield of "apparent" extract, whereas at temperatures of about 45° C. there is no increase. The author uses the word "apparent" because not more than 20—25 per cent. of this small increase is due to starch ; the bulk of it consists of such products as pentosans, proteins, and mineral matters, which might injuriously affect the quality of the beer. Moreover experiments on the large scale at Weihenstephan, although they established the fact of the increased density of the wort, yielded brews which were not quite satisfactory, either as regards the course of fermentation or the flavour of the product. Some breweries have reported favourably on the process, whilst others have had to give it up owing to the excessive coloration and reddish tint which it produced in their pale beers. It would seem that the doughing process has succeeded best in those breweries which work with waters highly charged with gypsum.—J. F. B.

Beers prepared by the so-called digestive mashing process. M. Rigaud. Z. ges. Brauw., 1909, 32, 53—55. (See also this J., 1909, 34, 154.)

LABORATORY experiments on worts prepared with preliminary doughing-in of the malt gave, with fine grists, increases in extract varying from 0.33 to 2.93 per cent., the mean being 1.45 per cent. Badly modified malts or those containing many hard and starchy corns exhibit the greatest increase of extract under this treatment, which also effects clarification of opalescent worts. Experiments made in the brewery with four not exceptionally tender malts showed increases in extract, due to doughing-in, varying from 0.81 to 1.35 per cent., the mean being 1.12 per cent. The finished beers from three of these malts have been examined and analysed, the principal variations caused by doughing-in being in the colour and protein-content of the beer. In the three cases, the colours, determined by means of N/10 iodine solution, were found to be 1.55, 1.5, and 1.5 respectively, where doughing-in had been resorted to, and 0.9, 0.9, and 1.1 in the corresponding beers prepared by the ordinary method. Such increase of colour can, of course, be counterbalanced by using slightly paler malts. The increases in the amount of protein per 100 grms. of beer were from 0.357 to 0.415, from 0.337 to 0.442, and from 0.298 to 0.386 grm., the increased percentages of protein in the total extract being 1.41, 2.88, and 2.13 in the three instances. The increased proportion of protein has no effect on the stability of the beer, whilst, on the other hand, it improves its head-retaining properties, its palate-fulness, and its nutritive value.—T. H. P.

Ammoniacal fermentation. J. Effront. Compt. rend., 1909, 148, 238—241.

WHEN distillery liquors are sown with a little garden soil, fermentation soon sets in and hydrogen and carbon dioxide are liberated. The fermentation is active in presence of a free supply of air and alkali carbonates ; it causes the disappearance of the amino-acids and the formation of ammonia and volatile fatty acids. Plate cultures in air and in a vacuum show the ammoniacal fermentation to be due to the symbiotic action of an anaerobic and an aerobic ferment. The first of these is the butyric acid bacteria isolated by Winogradski, which develops quite normally in an aerated medium in presence of other aerobic bacteria, but in pure culture is very sensitive to oxygen. A pure culture was sown in solutions containing per 100 parts : 2 of dextrose, 0.5 of yeast ash, 0.2 of potassium carbonate, and 3 of various amides. The following table shows the course of fermentation at 40° C. in an atmosphere of nitrogen :—

Amide.	1 day.			3 days.		8 days.		
	Dextrose.	Total nitrogen.	Nitrogen as ammonia.	Dextrose.	Nitrogen as ammonia.	Dextrose.	Total nitrogen.	Nitrogen as ammonia.
	mgms.	mgms.	mgms.	mgms.	mgms.	mgms.	mgms.	mgms.
Glycine	1800	519	14	840	230	0	541	520
Betaine	2050	365	28	1060	138	35	367	342
Asparagine	1400	561	221	420	419	18	558	553
Glutamic acid	1720	278	11	58	97	9	286	239
Distillery liquors	115	834	36	0	621	0	827	756

At the beginning, the ammoniacal fermentation proceeds parallel to that of the dextrose and the maximum of ammonia corresponds to the complete disappearance of the sugar. The amino-acids form only ammonia: betaine alone yields trimethylamine. From distillery liquors of sp. gr. 1.074, the ratio of ammonia to trimethylamine produced, is as 85:15. At the same time a mixture of acetic, propionic, and butyric acids is formed during fermentation, in proportions varying with the nitrogenous compound used:—

Amide.	Acids. Per cent. of total acidity.		
	Acetic.	Propionic.	Butyric.
Glycine	69.7	5.2	25.1
Betaine	58.1	11.6	30.3
Asparagine	6.0	62.3	31.6
Glutamic acid	4.9	10.1	85.0
Distillery liquor	25.1	26.8	48.1

Analogous results are obtained when the solutions are sown with ordinary earth instead of pure cultures; the fermentation may now be carried out in the air, and takes place more rapidly and completely. Other ferments hardly influence the change, and in particular the putrefying bacteria are paralysed by the aeration. Winogradski has shown that in a medium deprived of combined nitrogen the butyric ferment is able to assimilate nitrogen from the air. The constant presence of the butyric ferment and the products of protein hydrolysis in the soil suggests this fermentation as a ready means of transformation of nitrogen into an assimilable form.—E. F. A.

Ciders and perries; The rate of fermentation of —.
B. T. P. Barker. J. Agric. Sci., 1908, 3, 1—21.

THERE is a direct connection between the variety of apples and pears and the rate of fermentation of their juices; as a rule those varieties which ferment most rapidly do not yield ciders of high quality. The factor of variety, however, may tend to be obscured by other factors, such as the condition of ripeness of the fruit, the climatic conditions of the season and exposure to the sun, also the nature of the soil. The main factor in determining the rate of fermentation is the amount of nitrogenous matters present which are assimilable by yeast, and the effect of the other factors mentioned above appears to be due to their influence on this. The quantity of such matters is generally insufficient, and the natural rate of fermentation is consequently slower than when yeast-nutrients are added. As a rule, the rate of fermentation of juice from unripe fruit is relatively rapid. As the ripening progresses, changes in the composition of the juice occur which result in a diminution of the quantity of assimilable nitrogen, and the rate of fermentation becomes slower until the fruit is fully ripe. After that, as maturity merges into decay, the rate of fermentation of the juice gradually increases again. In determining this question of ripeness, the colour of the fruit, i.e., the degree of exposure to sunlight, is a more decisive factor than the actual age of the fruit. So far, no constituent of the juice, other than the assimilable nitrogenous matter has been observed to exercise a direct influence on the rate of fermentation, but the mucilaginous matters may indirectly in a mechanical manner, impede the fermentation. The factor of assimilable nitrogen appears to dominate any influence

which the relative fermentative activities of different varieties of yeast might be expected to exert; the sowing of specially active yeasts, therefore, has no effect on the rate of fermentation. Aeration of the juice, whether before fermentation, by "kieveing," or during fermentation, has a marked effect in increasing the rate of fermentation. The temperature of fermentation affects the rate in the usual manner. The average rate of fermentation of a given variety of juice is subject to variation from one season to another, but allowing for this, it should be possible by selection and blending of suitable juices to control the fermentation so as to produce sweet or dry types of cider as desired. As a general rule, the more rapid the fermentation proceeds, the further does attenuation proceed, although this is not invariably the case.—J. F. B.

Artificial oxylases and peroxydases. Martinand. See XXIV.

Denatured alcohol production of the United States. Oil, Paint, and Drug Rep., Feb. 1, 1909. [T.R.]

THE production of denatured alcohol during the year 1908 amounted to 3,874,625.62 wine gallons, as compared with 3,364,590.06 gallons during the year 1907. Calculated in terms of proof gallons, the production of 1908 exceeded 7,500,000 gallons. The output in 1908 consisted of 2,046,610.89 gallons of completely denatured and 1,828,014.73 gallons of specially denatured spirits. Owing to the anticipatory production of completely denatured spirits in 1907 there was a decline in 1908 in the production of this variety of alcohol of 219,977.68 gallons, while the output of specially denatured spirits in 1908 recorded a gain of 730,013.24.

PATENT.

Distillers' mash; Process for saccharifying —. F. Pampe, Halle-on-the-Saale, Germany. Eng. Pat. 26,582, Dec. 2, 1907. Under Int. Conv., Dec. 1, 1906.

THE malt is made into a thin mash, which, by slow filtration through cloth, is separated into malt paste and germ-free filtrate. The malt paste is used to effect the initial saccharification of the mash made from the other starchy materials used, the mash being then sterilised at a temperature of 68°—70° C., and cooled to about 60° C. The saccharification is then completed by means of the germ-free malt extract in presence of germ-free air, so as to ensure the absence of all injurious organisms from the mash.—T. H. P.

XVIII.—FOODS; SANITATION; WATER PURIFICATION, & DISINFECTANTS.

(A.)—FOODS.

Yeast; Adulteration of bakers' — [with starch]. A. Kopper. Chem.-Zeit., 1909, 33, 110.

THE adulteration of pressed bakers' yeast with starch not only defrauds the customer but the starch acts adversely on the activity of the yeast after keeping. Fermentation trials made with a yeast mixed with varying proportions of starch, after three days' keeping, showed that with 20 per cent. of starch, the fermentative activity was reduced by from 5 to 9 per cent., and with 50 per cent. of starch by 17—23 per cent. Microscopical examination of the yeast in the last case showed the presence of many

dead cells. Beer yeast is of little value for use by bakers on account of its low keeping qualities, which it imparts to articles in which it is used. The author suggests that the sale of brewers' yeast as distillery yeast for bakers should be prohibited.—E. F. A.

Proteins; Determination of the constitution of — by hydrolysis with hydrofluoric acid. Preparation of polypeptides. L. Hugounenq and A. Morel. *Compt. rend.*, 1909, 148, 236—238.

WHEN proteins are hydrolysed with hydrofluoric acid, containing less than 20 parts per 100 at the temperature of the boiling water bath, until the biuret reaction disappears, non-crystallisable products are obtained together with the arginine and lysine fractions. These new products are polypeptides of diamino-acids comparable with the synthetical products obtained by Fischer. They form well characterised picrates which serve to differentiate them from arginine and lysine. The authors have isolated the following picrates from the products of partial hydrolysis of pepsin. Diarginyl-arginine dipicrate forms voluminous crystals, m.pt. 207° C. (corr.); glutamyl-lysine picrate crystallises in prisms, m.pt. 216° C.; lysyl-lysine dipicrate separates in small plates, m.pt. 238—242° C. The products of the partial hydrolysis of gelatin yield arginylarginine picrate, which crystallises in bunches of needles, m.pt. 213° C. Groups formed by the uniting together of several molecules of arginine seem to play as important a part in the protein molecule as Kossel has shown them to do in the protamines. Hydrofluoric acid, stronger than 30 parts per 100, is able to completely hydrolyse proteins provided heating is continued long enough. If the acid, however, be too weak, even prolonged heating is not sufficient to hydrolyse certain polypeptides. The polypeptides isolated cannot have been formed from amino-acids by condensation caused by the mineral acid, since they are most abundant when hydrolysis is effected by a weak acid.—E. F. A.

Coffee plantations; Re-establishment of — by the introduction of a new species. J. Dybowski. *Compt. rend.*, 1909, 148, 232—233.

THE plantations of Arabian coffee (*Coffea arabica*) have been almost devastated in places by *Hemileia*, for which no cure or prevention has yet been found, and even in Java and Madagascar the plantations are producing less each year. Liberian coffee (*Coffea liberica*) withstands the disease better but has a lower market value. Hybrids of these two kinds have met with but indifferent success. A new coffee species (*Coffea congensis*) discovered growing wild on the shores of Oubangui, Central Africa, entirely resists *Hemileia*; it has a market value equal to that of the best Arabian coffee and a caffeine content of 1.19 per cent.; it promises therefore to be of the greatest value to the planters.—E. F. A.

Cocoa; New method of determining theobromine in —. A. Krentz. *Z. Unters. Nahr. Genussm.*, 1908, 16, 579—584.

FROM 1.5 to 2 grms. of the cocoa are mixed in a flask with 3 grms. of solid chloral alcoholate, and heated on the water-bath until the alcoholate is melted and a uniform mass is obtained by agitation. The hot melted mass is then extracted with small quantities of ether, each ether extract being filtered through a hardened filter. When about 40 to 50 c.c. of filtrate have been obtained, the solvents are distilled off, the chloral alcoholate in a tared flask under reduced pressure. The residue is then dried till of constant weight at 100—105° C. After cooling and weighing, the fat is extracted by means of carbon tetrachloride, and the insoluble theobromine is filtered off. The solvent is driven off from the filtrate, and the fatty residue is dried and weighed. The difference in the two weighings is taken as theobromine.—J. O. B.

Sodium benzoate as preservative for foodstuffs; Use of —. Report of U.S. "Referee Board." Oil, Paint, and Drug Rep., Feb. 1, 1909. [T.R.]

THE "Referee Board of Consulting Scientific Experts" has presented its report on the use of sodium benzoate

in foods to the Secretary of Agriculture; the main conclusions arrived at are as follows:—

1. Sodium benzoate in small doses (under 0.5 grm. per day) mixed with the food is without deleterious or poisonous action and is not injurious to health.

2. Sodium benzoate in large doses (up to 4 grms. per day) mixed with the food has not been found to exert any deleterious effect on the general health, nor to act as a poison in the general acceptance of the term. In some directions there were slight modifications in certain physiological processes, the exact significance of which modification is not known.

3. The admixture of sodium benzoate with food in small or large doses has not been found to injuriously affect or impair the quality or nutritive value of such food. (Compare Wiley, this J., 1908, 914).

(B).—SANITATION; WATER PURIFICATION.

Sewage purification and deodorisation; Application of electrolytic chlorine to — by the "orychlorides" process. S. Rideal. Faraday Soc., Feb. 9, 1909. [Advance proof.] (See also this J., 1907, 940.)

THE chlorine was produced in a new form of electrolyser, provided with a diaphragm, in order to obtain a more concentrated solution. The apparatus as used at the Guildford sewage works produced a liquid containing 8 per cent. of available chlorine, which was very stable and only slightly increased the amount of chlorides in the sewage treated. Using this solution on a sewage effluent, it was found that the addition of a quantity of available chlorine numerically equal to the five minutes' oxygen absorption figure, was more than sufficient to remove all *B. coli* from 10 c.c. in 2 hours and to leave available chlorine still present after 18 hours. Experiments were made on the large scale by the addition of electrolytic solution containing available chlorine equal to 25 to 35 per cent. of the oxygen absorption figure, to a septic tank effluent passing on to a percolating filter. The principal results obtained were that the addition of the chlorine solution did not interfere with the purification nor with the maturing of the filter; that the formation of surface growths on fine-grade material was prevented; and that the removal of growths in sprinklers, pipes, etc., could be easily accomplished. The experiments on deodorisation were made with varying amounts of orychloride solution containing 0.2 per cent. of available chlorine and it was found that an amount of available chlorine equal to 35 per cent. of the oxygen absorption figure removed all the sulphuretted hydrogen.—J. H. J.

Water; Purification of — by ozone. S. Rideal. Paper read before the Royal Sanitary Inst., Jan. 13, 1909. J. Gas Lighting, 1909, 105, 247—248.

THE author has examined the working of the installation for the sterilisation of water by ozone at the St. Maur water-works in Paris, where a large portion of the water-

supply of that city is treated. The water is drawn from the Marne, which receives a considerable amount of sewage pollution above the intake. The current for the ozonising plant is generated by means of a 45-h.p. steam engine and a Mordey alternator of 110 volts, and is changed by a transformer to a higher tension. The ozonisers are of the Siemens-Halske type and are placed in a dark, cool room. The energy consumption is about 57 Board of Trade units per million gallons of water treated, or 133 units including the energy required for compression. The cost is estimated at £d. per 1000 gallons, excluding interest, amortisation, and repairs. The author found that the physical characters of the water were greatly improved, the proportion of organic matter considerably reduced, and all but the more resistant spore forms of bacteria destroyed. No metallic contamination of the water resulted from any corrosion of the apparatus by the ozone, nor were any traces of oxides of nitrogen, chlorine compounds, or hydrogen peroxide formed. Of the ozone absorbed by the water, nearly 73 per cent. was immediately utilised in purification, 7 per cent. remained dissolved in the water, and about 20 per cent. passed off with the air current, which was used over again. The author concluded by discussing the relative advantages of the treatment of water by ozone, and its storage in reservoirs for a length of time (see this J., 1908, 873.)—A. S.

PATENTS.

Water; Purification of — by filtration, and apparatus for use therein. F. Candy, London. Eng. Pat. 9665, May 4, 1908.

THE invention relates to the production of a bacteria-arresting film on the upper part of a filter-bed, this film being formed of a substance, or substances, added to the water before the latter is passed on to the filter. The substances, such as clay, infusorial earth, milk of lime, aluminium sulphate, iron chloride or sulphate, etc., are placed in one or more tanks to which water is admitted from a side-tube on the water main; the emulsion or solution is then conducted from the tanks and mixed with the water in the main, the flow of water actuating an injector which is provided for this purpose. Stirrers are fitted in the tanks and are worked by means of a motor driven by water supplied from the main. The pressure of the water passing through the main should not be less than 7 lb. to the inch.—W. P. S.

XIX.—PAPER, PASTEBOARD, &c.

Hydrocellulose; Production of — by sulphuric acid. C. G. Schwalbe. Z. angew. Chem., 1909, 22, 155—156.

THE author criticises a paper by Büttner and Neuman on the above subject (this J., 1909, 105). He contests their view that elementary analysis is the best measure of the degree of resolution in the case of hydrocelluloses. Further, even if elementary analysis were sufficiently accurate, it would fail to make any distinction between hydrocelluloses and cellulose hydrates. The cupric-reduction method, on the other hand, is characteristic for hydrocelluloses and is in actual use in practice for the determination of the degree of hydrolysis. Büttner and Neuman also state that hydrocellulose is extremely resistant towards acids and alkalis. But it is pointed out that their results merely show that the residual hydrocellulose has the same elementary composition after boiling with acids as it had before, and take no account of the quantity of substance dissolved in the form of sugar, etc., as the result of the treatment with acid. Similarly, the author contests the statement as to the resistance of hydrocellulose towards alkalis. It is well known that sodium hydroxide at the boiling point dissolves a large proportion of the hydrocellulose and

that the cupric-reducing power of the residue is diminished. The author quotes some results which he has obtained by boiling Girard's hydrocellulose with 15 per cent. sodium hydroxide solution:—

Hydrocellulose.	Quantity of the sodium hydroxide solution of 15 per cent. strength.	Time of boiling.	Undissolved residue.
GRMS.	GRMS.	MIN.	PER CENT.
10	200	10	48
10	200	20	42
10	200	30	40
10	200	40	37
10	400	60	33

The blue colour produced by zinc chloride-iodine reagent with hydrocellulose is very transient and is rapidly removed by water, whereas the similar coloration with cellulose hydrates resists the action of water for a considerable time.—J. F. B.

Cellulose hydrates; The chemistry of —. C. G. Schwalbe. Z. angew. Chem., 1909, 22, 197—201.

IT is necessary to emphasise the difference between hydrolysis and hydration in the case of cellulose, although under certain conditions both may occur simultaneously. The hydrocelluloses, products of hydrolytic action, are generally characterised by free carbonyl groups which reduce Fehling's solution. The cellulose hydrates may be produced, with or without simultaneous hydrolysis, whenever cellulose is subjected to the action of alkalis, acids, or salts which exert a swelling or solvent influence in presence of water. According to Cross, hydration may take place in presence of water by mechanical action alone. Besides the cellulose hydrates artificially produced from the normal cellulose (anhydride), other types exist in nature which have never attained the dehydrated and polymerised condition of normal cellulose. These undeveloped types are sometimes included in the group of "hemicelluloses." The hydrated celluloses differ widely in their properties, but a high hygroscopic moisture is common to all; the hydrocelluloses on the other hand are distinguished by an abnormally low moisture-content. Some of the hydrates, *e.g.*, mercerised cotton, possess high tensile qualities, others, *e.g.*, the artificial silks, are mechanically deficient. These two groups also differ widely as regards their solubility in alkalis. Under certain conditions, the hydrated celluloses are resistant to esterifying influences to which the normal cellulose responds. All the hydrated celluloses are characterised by a diminished resistance to hydrolysis by acids, to an extent proportional to their "degree of hydration." Many methods have been proposed for the determination of the "degree of hydration" of a given cellulose: Vieweg measures the absorption affinity towards sodium hydroxide, Cross and Bevan utilise the thio-carbonate reaction and measure the viscosity of the product. Wübbner uses a colorimetric method with solutions of iodine in zinc chloride of different strengths, whilst Knecht measures the absorption of benzopurpurin under standard conditions. All these methods are open to objections, and the author has devised a method based on the increased susceptibility to hydrolysis by acids. The procedure is as follows: The "copper value" (cupric-reducing value) of the sample is first determined on 3 grms. of the substance in the manner previously described (see this J., 1907, 548). Another portion of the finely chopped substance is then boiled with a standard quantity of sulphuric acid of 5 per cent. strength, for 15 minutes with constant stirring. The acid is neutralised and the prescribed quantity of Fehling's solution is added without separating the hydrolysed fibre from the liquid. In this way a second "copper value" is obtained, and the difference between the two measures the hydrolysis which has taken place and which is proportional to the "degree of hydration" of the original cellulose. Some typical results are shown in the table:—

	Hygroscopic moisture.	Copper value after hydrolysis.	Copper value before hydrolysis.	Diff. rence.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENTIAL OILS, & EXTRACTS.

Tropine and its derivatives; Affinity values of —. V. H. Veley. Chem. Soc. Trans., 1909, 95, 1—8.

IN continuation of his previous work (this J., 1908, 1221), the author has found that tropine, the parent base of the atropine and cocaine alkaloids, has a lower affinity value than piperidine. Probably the stronger piperidine residue is modified by being conjoined to the weaker pyrrolidine residue, if the constitution recently advanced by Willstaetter is correct. Ecgonine possesses all the properties of an amphoteric electrolyte, and Willstaetter's view, that it is a betaine, or inner anhydride, is confirmed. Anhydroecgonine is a stronger base than ecgonine, and is approximately equal in affinity value to an aromatic betaine. Benzoylcegonine does not remain in combination with hydrochloric acid in weak solutions; it resembles caffeine in its basic functions. Cocaine is a relatively strong base, but is weaker than ammonia. The replacement of the carboxylic hydrogen in benzoylcegonine by the methyl group produces effects analogous to those previously observed with glycine. The affinity value of cocaine was found to be approximately, $k_b = 2.5 \times 10^{-7}$, by determining the mass of sodium hydroxide contained in a hydrolysed borax solution which was required to upset the equilibrium between a certain mass of cocaine combined with hydrochloric acid. The tropeines, atropine and homatropine, have an affinity value greater than $k_b = 1 \times 10^{-7}$, and $N/20$ solutions of their hydrochlorides show no appreciable hydrolysis when heated to boiling point.—J. O. B.

Yohimbé-bark (of the Cameroons), and its recognition in preparations. C. Griebel. Z. Unters. Nahr. u. Genussm., 1909, 17, 74—78.

THE presence of powdered Yohimbé-bark in preparations may be recognised by means of the microscope and chemical tests. Under the microscope, the powder is seen to contain large, but narrow, bast fibres, which are free from pores, and entirely free from schlerenchymatous cells. Cork cells are present, which are strongly compressed, porous, and generally free from pigment. The cells of the parenchyme have brown walls, contain practically no starch, and show clusters of reddish-brown particles. For the chemical tests, an extract is made with ether in the presence of an alkali, and the solution evaporated. The presence of yohimbine in the residue can be shown by the following reagents. With strong sulphuric acid no coloration is obtained, but the addition of a crystal of potassium bichromate causes a blue-violet streak, changing to bluish-grey and then to greenish-brown. Erdmann's reagent (sulphuric acid containing a small quantity of nitric acid) causes a dark grey-blue colour, passing quickly to yellowish-green. Fröhde's reagent (5 mgrms. of sodium molybdate in 1 c.c. of strong sulphuric acid) causes an immediate grey-blue colour, quickly turning to dark blue, finally to green. Mandelin's reagent

(1 grm. of ammonium vanadate in 200 c.c. of strong sulphuric acid) brings about a fine dark blue colour with a trace of violet in the residue itself, whilst the reagent turns to an orange colour, subsequently becoming brick-red.—F. SHDN.

δ-Coniceine; Synthesis of inactive —. K. Löffler and H. Kaim. Ber., 1909, 42, 94—107.

THE authors prepared trichloro-α-picolylmethylalkine by the condensation of α-picoline and chloral. The product was treated with alcoholic potassium hydroxide when pyridylacrylic acid was obtained, with a small quantity of α-pyridyl-lactic acid. Pyridylacrylic acid was reduced with sodium and alcohol with the formation of piperidylpropionic acid, $C_5H_{10}N.CH_2.CH_2.COOH$. The hydrochloride of the ethyl ester of piperidylpropionic acid melts at 122° C.; the ethyl ester boils at 143—144° C. at 21 mm., and has the sp. gr. 1.0214 at 15°/4° C.; the hydrochloride of the free acid melts at 188° C.; and the free acid, $C_5H_{10}N.CH_2.CH_2.COOH.2H_2O$, crystallises from water in large tablets, and melts at 147—148° C. When piperidylpropionic acid is heated in a vacuum to 200° C., 2-piperolidone, $C_5H_{13}NO$, distils over. This liquid lactone is easily soluble in water and alcohol, boils at 126—127° C. at 12 mm., and at 263°—264° C. at the ordinary pressure. α-Pyridyl-lactic acid was reduced with sodium and alcohol, and after further treatment 3-hydroxy-2-piperolidone, $C_5H_{13}O_2N$, was obtained. This substance melts at 129—130° C., boils at 183—184° C. at 18 mm., and at 304°—305° C. at the ordinary pressure. This was reduced with sodium and alcohol with the production of piperolidine,

Piperolidine in its physical constants and in the melting-point of its salts is identical with δ-coniceine, and the constitution of that alkaloid, as ascertained by Lehlmann (Annalen, 259, 193) is thus confirmed.—F. SHDN.

β-Coniceine (1-allylpiperidine); Synthesis of —. K. Löffler and G. Friedrich. Ber., 1909, 42, 107—116.

BY the treatment of α-picoline with acetaldehyde, α-picolylmethylalkine is produced. This can be reduced with sodium and alcohol to picepolymethylalkine, boiling at 222°—228° C., and melting at 56°—58° C. after crystallising from light petroleum. α-Picepolymethylalkine was treated with phosphorus pentoxide at 100° C. in a current of hydrogen, the product dissolved in ice-water, the liquid made alkaline, and the free base distilled with steam. The product was a colourless oily base, which on treatment with picric acid gave two salts, one solid and the other oily. The salts were separated by crystallisation from alcohol, and a solid picrate obtained melting at 113—114.5° C., which was decomposed with alkali in order to obtain the free base. The base obtained in this way was inactive α-allylpiperidine, $C_8H_{15}N$. It boils at 168.5°—170° C. at 753 mm., and has the sp. gr. 0.8716 at 15°/4° C.; the hydrochloride melts at 206°—207° C. This base was resolved into its optical isomerides by crystallising the bitartrate from water. The dextro-rotatory base, d-α-allylpiperidine, forms a bitartrate melting at 62—

—J. F. B.

63° C. The free base melts at 38.5°—39° C., and has $[\alpha]_D^{25} = +49.89$ at 45° C. The hydrochloride melts at 181—182° C. The laevo-rotatory base, *l*- α -allylpiperidine, was identified as β -coniceine (this J., 1905, 1186). The oily picrate associated with the picrate of inactive α -allylpiperidine, m. pt. 113—114.5° C., was found to contain a base described as *iso*- α -allylpiperidine. The hydrochloride of *iso*- α -allylpiperidine melts at 186—187° C., the free base boils at 166.5—168.5° C., and has the sp. gr. 0.8695 at 15.4° C. By means of tartaric acid, *d*-*iso*- α -allylpiperidine was obtained, which had the specific rotation, $[\alpha]_D^{25} = +24.81$ at 15° C., and formed a hydrochloride melting at 189—190° C. β -Coniceine was heated to 100° C. under pressure with hydriodic acid, and reduced with zinc dust at 0° C. The base obtained in this way was proved to be conine.—F. SUDN.

Essential oils: Constituents of —. Constitution of camphene and its oxidation by means of ozone. F. W. Semmler. Ber., 1909, 42, 246—252.

Crude camphene when oxidised with ozone gives rise to but one ozonide, $C_{10}H_{16}O_3$, showing that crude camphene is not a mixture of isomerides but a single substance. Camphene ozonide is a viscous oil, which is decomposed on steam-distillation, or by distilling in a vacuum. When the ozonide is distilled with steam, camphenilone passes over, whilst a hydroxy-acid, $C_9H_{14}O_3$, remains behind. Camphenilone melts at 40° C., boils at 73°—75° C. at 10 mm., has the sp. gr. 0.9800 at 20° C., and $n_D^{20} = 1.469$. The semicarbazone melts at 223° C. The acid, $C_9H_{14}O_3$, proved to be β -hydroxycamphenilonic acid, which is readily converted into the lactone, $C_9H_{14}O_2$. The lactone boils at 126°—128° C. at 10 mm., and sets to large tabular crystals melting at 95°—96° C. The acid, $C_9H_{14}O_3$, on distilling in a vacuum decomposes into the lactone mentioned above, and an acid, $C_9H_{14}O_2$, which boils at 136°—140° C. at 10 mm., and has the sp. gr. 1.028. The author concludes that camphene has the constitution represented by the formula:

—F. SUDN.

Grignard synthesis: Action of phenyl magnesium bromide on camphor. H. J. M. Creighton. Proc. Nova Scotia Inst. Sci., 1908, 11, 593—597. (See also this J., 1909, 682).

A SOLUTION of Japanese camphor in $\frac{1}{2}$ times its weight of ether, was allowed to drop into the calculated quantity of the phenyl magnesium bromide, and the mixture was maintained at 60° C. under a reflux condenser all night, the mixture being poured on to crushed ice, containing an excess of dilute hydrochloric acid to dissolve the precipitated magnesium hydroxide. The oil was separated from the resulting liquid, treated with sodium bisulphite, to remove any undecomposed ketone, and then washed with water and dehydrated over calcium chloride. After expelling the unaltered camphor at 205°—210° C., the product was distilled *in vacuo*, at 150° C., furnishing a pale yellow oil, amounting to about 25 per cent. of the theoretical yield. This oil has a flavour of balsam, and is miscible with alcohol, ether, and chloroform. The sp. gr. is 0.977, b. pt. 143°—145° C. at 14 mm. pressure, and 258°—260° C. at 760 mm. The mean molecular weight is 232.1, as compared with 239.17 (cal.) for $C_{16}H_{22}O$; and the percentage composition is: carbon, 83.89; hydrogen, 9.28; oxygen (by diff.), 6.83 per cent.; specific rotation (in alcohol solution) $[\alpha]_D^{25} = 7.55$. The product is a tertiary alcohol, analogous to methylborneol, and should therefore be termed phenylborneol.—C. S.

Chemotherapeutics: Present condition of —. P. Ehrlich. Ber., 1909, 42, 17—47.

THE author describes the difference between serum-therapeutics, in which the agents used are those developed in the organism, and chemotherapeutics in which synthetic remedies are employed. Synthetic remedies are especially useful in malaria and diseases caused by

trypanosomes, etc. The paper is concerned mainly with the attempts to prepare substances, which while having no appreciable injurious action on the organism, yet are capable of completely and readily destroying trypanosomes—parasites which are the cause of numerous diseases of animals, and also of sleeping sickness. The improvements and developments which have followed since the introduction of atoxyl (sodium *p*-amino-phenylarsinate) are described and discussed. In arsenophenylglycine, it is stated, a compound has been obtained which in thousands of trials on lower animals infected with trypanosomes, has never failed to effect a cure. The author is of the opinion that further work in chemotherapeutics will be more fruitful still if based on the view that independent partial functions ("chemoceptors") may be differentiated in the cell itself, and that the activity of therapeutic agents is governed by the nature of the interaction (combination, etc.) between such agents and the "chemoceptors." (See also this J., 1902, 789; 1908, 710, 1130, 1175; 1909, 169).—A. S.

Suprarenine and related substances: New synthesis of —. K. Böttcher. Ber., 1909, 42, 253—266.

IN synthesising suprarenine and allied substances, the author has isolated a number of compounds. The methylene ether of vinylpyrocatechol,

(obtained by the action of methylmagnesium iodide on piperonal) was dissolved in carbon tetrachloride, and chlorine passed through, when 3,4-methylenedioxy- β -chloro- α -hydroxyethane was produced. This substance crystallises in needles melting at 95° C. It was treated with phosphorus pentachloride, which was distilled off under reduced pressure, and the residue dissolved in acetone. Water was added slowly, the liquid carefully neutralised with sodium carbonate, extracted with ether, and the ethereal solution evaporated. The substance thereby produced is α -[3,4-dihydroxyphenyl]- β -chloro- α -hydroxyethane. After careful crystallisation from benzene, it decomposes at 100° C., and is not very stable. The same product can be produced by a similar reaction from methylenedioxyphenyl- α , β -dichloroethane. α -[3,4-Dihydroxyphenyl]- β -bromo- α -hydroxyethane is produced by analogous reactions and decomposes at 92°—93° C. Either of the above halogen-hydrins is converted into suprarenine by the action of methylamine. 3,4-Methylenedioxyphenyl- β -bromo- α -hydroxyethane was heated with sulphuryl chloride, and the excess of the latter driven off at reduced pressure. The residue was crystallised from dilute alcohol and formed long needles melting at 128°—129° C.; it was found to be α -[3,4-methylenedioxy-chlorophenyl]- β -bromo- α -hydroxyethane. The corresponding β -chloro product melts at 126°—127° C. *pseudo*-Safrol chlorohydrin, $\text{CH}_2 < \text{O}_2 > \text{C}_6\text{H}_3 \cdot \text{C}(\text{OH})(\text{CH}_3) \cdot \text{CH}_2\text{Cl}$, was produced by the action of chlorine on *pseudo*-safrol dissolved in carbon tetrachloride. This was treated with phosphorus pentachloride and acetone as before, and the chlorohydrin thus obtained was allowed to interact with methylamine to form α -methylsuprarenine. This base was purified by dissolving it in hydrochloric acid and precipitating with ammonia, when it formed a bright yellowish-brown powder. *iso*Safrol dichloride, $\text{CH}_2 < \text{O}_2 > \text{C}_6\text{H}_3 \cdot \text{CHCl} \cdot \text{CHCl} \cdot \text{CH}_3$, was prepared by the action of chlorine on *iso*safrol, and boiled at 164°—165° C. at 11 mm. By treatment with phosphorus pentachloride and acetone as before, α -[3,4-dihydroxyphenyl]- β -chloro- α -hydroxypropane was produced, which was crystallised from ethyl acetate and decomposed at 104°—105° C. The β -methylsuprarenine produced therefrom was a yellow powder. When the methylene ether of vinylpyrocatechol is treated with hydrogen bromide, methylenedioxybromophenyl- β -bromo- α -hydroxyethane is produced which melts at 157°—158° C. This substance on oxidation yields monobromopiperonylic acid, m. pt. 201°—202° C. It was treated with phosphorus pentachloride, and finally a monobromosuprarenine, $(\text{OH})_2\text{C}_6\text{H}_2\text{Br} \cdot \text{CH}(\text{OH}) \cdot \text{CH}_2 \cdot \text{NH} \cdot \text{CH}_3$, was obtained as a light-brown powder. The synthetic suprarenine formed methylamine on warming with sodium hydroxide, and gave a green coloration with

ferric chloride in dilute hydrochloric acid. Its physiological action resembled that of natural suprarenine. (See this J., 1909, 41.)—F. SHDN.

Volatilisation and sublimation, especially of high-molecular carbon compounds, at low temperatures, in a vacuum. C. J. Hansen. Ber., 1909, 42, 210—214.

The author has determined the temperature at which appreciable volatilisation of some high-molecular carbon compounds occurs in the cathode light vacuum (compare Krafft, this J., 1908, 21, 68). Some of the results are shown in the following table:—

Substance.	Temp.	Time.	Weight taken.	Loss of weight.
	°C.	hours.	grms.	grms.
Lauric acid	22	6	0.8215	0.0005
Myristic acid	27	6	0.4263	0.0003
Palmitic acid	32	12	0.4840	0.00012
Stearic acid	38	12	0.6266	0.00012
Laurone	40	10	0.4935	0.0001
Myristone	46	10	0.4638	0.0001
Palmitone	52.7	13	0.5802	0.0001
Stearone	58	13	0.5642	0.00003
Dotriacontane	63	14	0.6942	0.0002

Phenanthrene lost 34 per cent. of its weight in 12 hours at 36° C., and 12 per cent. in 12 hours at the ordinary temperature (about 20° C.). Anthracene lost 1 per cent. in 6 hours at 35° C. Phenanthraquinone lost 0.15 per cent. and anthraquinone 0.08 per cent. in 10 hours at 36° C. From 0.4547 grm. of alizarin, 0.2 mgrm. sublimed in 12 hours at 55° C. Maleic acid was sublimed without decomposition at about 80° C.; citraconic acid was sublimed at 40° C., but was converted partially into the anhydride. Phthalic acid began to decompose at 120° C., but by heating three boats, each containing 1 grm. of the coarsely powdered acid, for 48 hours at 115°—117° C., 1 grm. of pure phthalic acid was obtained as sublimate. All the temperatures given refer to the vacuum of the cathode light. (See also Kempff, this J., 1908, 1049.)

—A. S.

a-Naphthol; New reaction for —. Dané. L'Union. pharm., 1909, 50, 1.

On adding a few drops of formaldehyde solution to a solution of a few cgrms. of *a*-naphthol in caustic alkali, a green colour is formed in a few minutes in the cold, and at once on warming; this changes to deep blue. On exposing the blue solution to the air, a brown insoluble substance separates. With *β*-naphthol, no such reaction occurs; even after several months' contact no colour is formed, but a slight amount of insoluble substance is deposited. Although the blue colour commences to form on the surface of the mixture, it is not dependent on oxygen: it occurs in a precisely similar manner in a solution of *a*-naphthol protected from the atmosphere by a layer of vaseline oil.—J. O. B.

Nitrates and hydrocyanic acid; Loss of — during the drying of plants. E. Couperot. J. Pharm. Chim., 1909, 29, 100—102.

DIFFERENT portions of the plants of three varieties of lder (*Sambucus nigra*, *S. laciniata*, and *S. racemosa*) were dried by exposure to air and the amounts of hydrocyanic acid and nitrates determined. The amount of these substances in the fresh plant was also ascertained. A table is given showing the amounts of each present. It was found that drying the plant in the air caused a loss of one-fifth or even one-half of the hydrocyanic acid or nitrate originally present. If the plant was dried quickly by heating to 60° C., there appeared to be no loss, indicating that during the slow drying, a secondary fermentation must go on.—F. SHDN.

Hydrocyanic acid; Formation of —, during the action of nitric acid on phenols and quinones. A. Sewewetz and L. Poizat. Compt. rend., 1909, 148, 286—288.

THE formation of hydrocyanic acid by the action of nitric acid on organic substances appears to occur only when there is a phenolic or quinonic group present. The

author considers that an ortho- or para-nitroso-derivative of the phenol is first formed, which can function as an ortho- or para-quinoneoxime. This is oxidised in such a way as to produce mesoxalic acid and its oxime, or oxalic acid and the monoxime of dihydroxytartaric acid; and the hydrocyanic acid is derived from the oxime.

—J. T. D.

Cyanuric acid; New method of preparing — from urea. R. von Walther. J. prakt. Chem., 1909, 79, 126—128.

28X grms. of urea were mixed with 20 grms. of anhydrous zinc chloride and heated to about 220° C. After cooling, the reaction product was treated with dilute hydrochloric acid, and the crystals which separated were purified by recrystallisation from hot water. The yield of cyanuric acid thus obtained was 62 per cent. of the theoretical quantity and was not improved by varying the amount of zinc chloride used.—A. S.

Ethers; New method of preparation of —. J. B. Senderens. Compt. rend., 1909, 148, 227—229.

By the catalytic action of precipitated aluminium oxide on alcohol vapour, the alcohol is dehydrated, forming an ethylene hydrocarbon. In the case of acids, dehydration involves the participation of two molecules, carbon dioxide and an ether being formed: thus, $2\text{CH}_3\text{CO}_2\text{H} = \text{H}_2\text{O} + \text{CO}_2 + \text{CH}_3\text{COCH}_3$. It is now found, using alumina obtained by precipitating sodium aluminate with sulphuric acid, that if the temperature is maintained at 240°—260° C., the formation of ethylene from alcohol is very small; two molecules of alcohol become involved in the dehydration and ether is formed. The vapours, after passing over the heated alumina, are condensed to a liquid, which separates into two layers. The upper layer when separated by decantation, consists of ether so far dehydrated that 83.5 per cent. distils below 60° C. The process is applicable to 95 and 85 per cent. alcohol as well as to absolute alcohol. Dimethyl ether and dipropyl ether have also been obtained in a similar manner.—E. F. A.

Dihydroxyacetone; Colour reactions of —. G. Denigés. Compt. rend., 1909, 148, 172—173.

DIHYDROXYACETONE, whether prepared synthetically or by the action of the sorbose bacterium on glycerin, gives colour-reactions with certain phenolic substances and alkaloids—resorcinol, thymol, *β*-naphthol, codeine and other opium-alkaloids. The reagent in 5 per cent. alcoholic solution (0.1 c.c.), the solution of dihydroxyacetone, containing not more than 1 grm. per litre (0.4 c.c.), and exactly 2 c.c. of sulphuric acid of sp. gr. 1.84 are mixed in a test-tube, and after one or two minutes at the ordinary temperature, the tube is heated in boiling water for two minutes. With codeine, a deep greenish-blue colour is struck; with *β*-naphthol, a green colour with greenish fluorescence; with resorcinol, in the cold, a colour resembling that of solutions of bichromates; with thymol, also in the cold, a blood-red or claret colour, becoming rose at very great dilutions. All of these reactions are extremely delicate. The colorations with the different morphine alkaloids (morphine, codeine, oxydimorphine, apomorphine) permit of distinguishing these alkaloids readily from one another.—J. T. D.

Dihydroxyacetone; Reactions of —. G. Denigés. Compt. rend., 1909, 148, 282—283.

CERTAIN colour reactions are given by dihydroxyacetone in presence of bromides (and hence by glycerin which has been converted into dihydroxyacetone by addition of bromine) which are not given by dihydroxyacetone alone. The reagents the author has used, amongst others, are especially guaiacol, salicylic acid, and gallic acid. Into a test-tube is put 0.1 c.c. of a 5 per cent. solution of the reagent, 0.1 c.c. of 4 per cent. solution of potassium bromide, 0.4 c.c. of the solution containing dihydroxyacetone (not stronger than 1 grm. per litre), and 2 c.c. of sulphuric acid of sp. gr. 1.84. The substances are mixed by shaking, and the tube is immersed for two minutes in boiling water. Guaiacol gives a deep-blue tint in a solution containing 0.1 grm. per litre, becoming more rose-coloured

as the solution becomes more dilute. Salicylic acid strikes a strawberry red colour, and gallic acid a deep violet. (See also preceding abstract.)—J. T. D.

Iodoform; *Formation of* —, G. Guerin. *J. Pharm. Chim.*, 1909, 29, 54–55.

IN the presence of ammonia and a caustic alkali, iodoform is formed by the action of iodine on carbonic acid. From 5 to 6 grms. of potassium iodide and 2 or 3 grms. of an alkali carbonate are dissolved in 50 c.c. of water, then 10 c.c. of ammonia solution and the same quantity of caustic alkali solution are added. The mixture is treated with a solution of an alkali hypochlorite, which causes the appearance of black flocks of nitrogen iodide; when this no longer readily disappears, on agitation, after adding more hypochlorite, a large excess of ammonia is added at once which brings about the almost instantaneous conversion of nitrogen iodide into iodoform. If the hypochlorite solution employed is very dilute, there is no previous separation of nitrogen iodide. The reaction appears to occur as follows:

—J. O. B.

Calcium; *Action of alcohols on metallic* —, F. M. Perkin and L. Pratt. *Chem. Soc. Proc.*, 1909, 25, 18.

WHEN calcium is added to alcohols, reaction ensues and the alkoxide, $\text{Ca}(\text{OR})_2$, is produced (this J., 1908, 39). The reaction, however, is generally slow, but is greatly facilitated by heat. Calcium hydride reacts more readily than metallic calcium, but the product is less pure than when the metal is employed, owing to impurities in the calcium hydride. Calcium ethoxide is soluble in ethyl alcohol, and crystallises with two molecules of alcohol of crystallisation. Other alkoxides are not so readily prepared, owing to their insolubility in the alcohols. Calcium ethoxide has been employed satisfactorily for organic condensations in place of sodium ethoxide.

Purity of lactose. Hillringhaus and Heilmann. See XVI.

PATENTS.

[*Theobromine double salts*] *Pharmaceutical products*; *Manufacture of new* —, G. W. Johnson. London. From Verein. Chininfabr. Zimmer und Co., Frankfurt, Germany. Eng. Pat. 6439, March 23, 1908.

DOUBLE salts of theobromine-sodium and halogen salts of the alkalis are obtained by the interaction of molecular proportions of the components. These double salts are readily soluble in water. Example: 18 parts of theobromine are dissolved in an aqueous solution of 4 parts of sodium hydroxide, 5.85 parts of sodium chloride are added, and the solution, after filtering if necessary, is evaporated.—A. S.

Nerol; *Process for the extraction of* — from oil of *Helichrysum angustifolium* and other species of *Helichrysum*. Heine and Co. Fr. Pat. 394,496, Sept. 21, 1908. Under Int. Conv., Sept. 21, 1907.

THE claims are for the extraction of nerol from oils of species of *Helichrysum*, especially *H. angustifolium*, by methods similar to those used for the extraction of this alcohol from petitgrain oil (see Fr. Pat. 326,658 of 1902; this J., 1903, 819).—A. S.

p-Aminophenylarsinic acid; *Process for preparing sulphur derivatives of* —, Farbwerke vorm. Meister, Lucius, und Brüning. Ger. Pat. 205,617, Nov. 23, 1907.

AQUEOUS or alcoholic solutions of *p*-aminophenylarsinic acid, its homologues or derivatives, or the corresponding arsenious oxide compounds, are converted into sulphur derivatives by treatment with hydrogen sulphide. The compounds have the constitution: $\text{R}_1\text{R}_2\text{N} \cdot \text{C}_6\text{H}_4 \cdot \text{AsS}$; $\text{R}_1\text{R}_2\text{N} \cdot \text{C}_6\text{H}_4 \cdot \text{AsS}_2$; $(\text{R}_1\text{R}_2\text{N} \cdot \text{C}_6\text{H}_4 \cdot \text{As})_2\text{S}_3$. They possess higher toxicity than the corresponding oxygen compounds,

but also have a stronger action on trypanosomes. The preparation of *p*-aminophenylarsenic sulphide, *p*-acetaminophenylarsenic sesquisulphide, and phenylglycimarsenic disulphide is described in the specification. Thus, 60 grms. of *p*-aminophenylarsinic acid are dissolved in 3 litres of water and 160 c.c. of hydrochloric acid (sp. gr. 1.49), and the solution saturated with hydrogen sulphide; the precipitated *p*-aminophenylarsenic sulphide, $\text{NH}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{AsS}$, is dried and freed from sulphur by extraction with carbon bisulphide.—T. F. B.

α-Naphtholarsinic acid; *Process for preparing* —, W. Adler. Ger. Pat. 205,775, Nov. 6, 1907.

α-Naphthylaminoarsinic acid, obtained by heating a mixture of *α*-naphthylamine and arsenic acid to 190° C., is diazotised, and the solution of the diazo compound treated with steam, when it is converted into *α*-naphtholarsinic acid.—T. F. B.

Camphene; *Process for preparing* —, Act.-Ges. f. Anilinfabr. Ger. Pat. 205,850, Oct. 10, 1907.

THE semi-liquid compounds resulting from the action of aniline or its homologues on pinene hydrochloride are decomposed by means of acids or salts into camphene and aniline or a homologue; a diluent may be added if desired. The aniline or other base is separated from the camphene by distillation with steam, the last traces being removed by washing with acids.—T. F. B.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

Photographic developer "Pyramidal Vindonissa" [dihydroxydiphenylamine]. L. P. Clerc. Bull. Soc. Franç. Phot., 1909, 25, 48–55.

p-p'-DIHYDROXYDIPHENYLAMINE, prepared by the condensation of quinol with *p*-aminophenol, is applicable, in the form of its normal sulphate, as a photographic developer. In aqueous solution the base is rapidly oxidised, but its sulphate is quite stable in solution. It is an energetic photographic developer in presence of alkalis; formulae for the various processes are given in the paper.—T. F. B.

Colour photography; *Experimental investigation of Lippmann's process of* —, H. E. Ives. Z. wiss. Phot., 1908, 6, 373–401. Chem. Zentr., 1909, 1, 335.

THE author concludes from the results of his experimental study of Lippmann's process of colour photography (this J., 1891, 483; 1893, 464; 1895, 65), that the purity of the reflected monochromatic light is increased by decreasing the content of silver bromide in the sensitive film. For the reproduction of mixed colours, development

with quinol (hydroquinone) is suitable, followed by bleaching. The colours of natural objects are reproduced better by coarse-grained than by fine-grained films, whilst the latter are more suitable for pure colours. A reflecting film of silver can be used in place of the mercury mirror. Lippmann's films, being capable of reproducing pure colours, are well suited for use in the three-colour process.

Tanning and adsorption compounds of gelatin. Lüppe-Cramer. See XIV.

XXII.—EXPLOSIVES, MATCHES, &c.

Cheddites containing ammonium perchlorate in place of potassium chlorate; Report on —. Mém. des Poudres et Saltpêtres, 1907—1908, 14, 206—229.

THE explosives had the following compositions:—No. 1—Ammonium perchlorate (82), dinitrotoluene (13), and castor oil (5 parts). No. 2—Ammonium perchlorate (50), sodium nitrate (30), dinitrotoluene (15), and castor oil (5 parts).

Rate of combustion in the open.—No. 1—The rates of combustion in mm. per second at the external temperatures stated, were as follows: 2°C , 4.5 mm.; 7°C , 100 mm.; 17°C , 125 mm. No. 2—Under ordinary conditions of temperature, combustion did not take place in the open, even when the explosive, before being tested, had been kept in a dry atmosphere.

Detonation by shock.—A weight of 30 kilos, with a striking surface of 16 sq. cm. was allowed to fall from a height of 4.5 m. upon 100 grms. of each explosive spread over an area of 35 cm. by 10 cm. Cheddite No. 60 was used as a standard of comparison. The quantity which exploded in each instance was as follows:—No. 1, 17 grms.; No. 2, 13 grms.; cheddite No. 60, 27 grms. From the point of view of transmission of detonation by shock, these explosives present greater security than cheddite itself.

Special dangers of ammonium perchlorate.—Clothing impregnated with ammonium perchlorate burns more rapidly than that impregnated with potassium chlorate, though not so fiercely as when sodium chlorate is used. Explosives containing the last ingredient have, however, been authorised for manufacture in France, as it was found that this objection could be overcome. Ammonium perchlorate, as regards sensitiveness to shock, stands almost on a level with picric acid. As an explosive, ammonium perchlorate is considered to possess a considerable coefficient of safety. It is, however, pointed out that owing to the possibility of dangerous chemical reactions occurring between ammonium perchlorate and potassium and sodium chlorate, the manufacture of these two types of explosives require to be completely separated.

Experiments on heating.—A pulverised sample of electrolytic ammonium perchlorate was heated continuously at 110°C . for ten months. Up to twenty days the loss was only 0.33 per cent. after allowing for moisture. From that time onwards, a steady decrease of weight was apparent, amounting to 23 per cent. at the end of ten months. No loss in weight could be detected on heating at 40°C . for seven months. Samples of the two explosives mentioned, similarly treated, showed a loss in weight equivalent to the dinitrotoluene contained in the sample.

The two explosives are considered as chemically stable under ordinary conditions of storage. *Gaseous products reduced on explosion.*—Experiments carried out under conditions simulating those present in mining showed that explosive No. 1 produced a very considerable quantity of disagreeable acid fumes. In the case of explosive No. 2 (containing sodium nitrate), the disagreeable effect was not nearly so marked, and it is considered probable that a explosive containing 46 per cent. of ammonium perchlorate and 34 per cent. of sodium nitrate would be more satisfactory from this point of view.

Closed vessel experiments.—The following pressures per sq. cm. were registered for the charge densities mentioned:—No. 1: 1, 975 kilos.; 0.2, 2546; 0.25, 3123 kilos. No. 2: 0.1, 52 kilos.; 0.2, 1942; 0.25, 2426 kilos. *Velocity of tonation.*—No. 1—With a density of 0.69, the velocity detonation was found to be 2795 m. per second, rising

to a maximum of 4020 m. at a density of 1.04, and falling from this point to 3768 m. at a density of 1.25. No. 2—With a density of 0.88, the velocity was 2655 m. The maximum velocity (3361 m.) was obtained at a density of 1.04, and from this point the velocity fell to 3006 m. at a density of 1.34. *Sensitiveness to detonation by fulminate.*—With a detonator containing 1.5 grms. of fulminate, detonation of the explosives was always complete if the density of the explosive did not exceed 1.3. A detonator containing 0.5 gm. of fulminate caused complete detonation when the density of the explosive was not greater than 1.1. A detonator containing 0.3 gm. of fulminate completely detonated the explosive when the density was not more than 0.9. The sensitiveness to detonation was also influenced detrimentally by a low external temperature, and by a hardening of the cartridge. *Hardening of the explosive.*—In addition to hardening, properly so called, there is also contraction in the material of the cartridge, and the two phenomena are not necessarily related. For instance some varieties of cheddite harden to a very considerable extent, but contract very little. The hardening is apparently due to re-oxidation of the castor oil, owing to access of air, and the large surface of castor oil exposed on account of the fine state of division of the chlorate. Experiments with a viscometer showed that castor oil which originally ran at the rate of 20 c.c. per hour from the viscometer, fell in rate of flow to 17.5 c.c. after 1 month's heating at 60°C ; whilst the same castor oil heated during the same time in admixture with potassium chlorate, and then extracted with ether, had only a rate of flow of 2 c.c. due to increased viscosity. Side by side, a contraction goes on, at times to such an extent, that the original density of 1.23 increased to 1.44. It is to this latter fact (increase of density), that lack of detonation is to be ascribed. A reference to the influence of increase of density on unsatisfactory detonation referred to above, makes this point clear. *Detonation in lead blocks (Abel).*—The lead blocks were 255 mm. in diameter, and 288 mm. high. The hole was 28 mm. in diameter, and 180 mm. deep. 10 grms. of explosive were used, and a detonator containing 2 grms. of fulminate. The increase of volume was 226 c.c. equal to 22.6 c.c. per gm. Dynamite No. 1, in similar blocks, gave an equivalent of 25.6 and 26.3 per gm.—G. W. McD.

Explosive; New — termed "carbite"; and three types of dynamite containing dinitrotoluene; Reports by the Commission des Substances Explosives (France) on requests for sanction for the manufacture of —. Mém. des Poudres et Saltpêtres, 1907—1908, 14, 176—177, 185—187, 190—192.

(1). "CARBITE" consists of nitroglycerin (25), potassium nitrate (34), flour (38.5), barium nitrate (1), powdered bark (1), and sodium carbonate (0.5 parts). The resistance to moisture was found to be good, though the heat test was only medium. Permission for the manufacture of the explosive was granted. (2). The explosives were of the following compositions: (A). Nitroglycerin (85), nitrocotton (8), and dinitrotoluene (7 parts). (B). Nitroglycerin (75), nitrocotton (5), dinitrotoluene (8), potassium nitrate (10), and cellulose (2 parts). (C). Nitroglycerin (50), nitrocotton (3), dinitrotoluene (7), potassium or sodium nitrate (34), cellulose or flour (5.8), and red ochre (0.2 parts). At the end of seven months of storage the samples were in a good state of preservation, though explosive (C), containing sodium nitrate, showed slight traces of exudation. In view of the fact that the question of the use of dinitrotoluene as a constituent of nitroglycerin explosives for the purpose of preventing freezing, should be further studied in all its bearings, only a few thousand kilos. were authorised for manufacture.

—G. W. McD.

PATENTS.

Explosives. Anglo-French F. and S. Ltd., and J. B. Edwards, London. Eng. Pat. 24,025, Oct. 30, 1907.

THE object of the invention is to render the combustion of the explosive more regular and complete, and to prevent the production of a flame at the muzzle of the gun. For this purpose the explosive is mixed with from 2 to 7

per cent. of carnauba wax and 2 per cent. of sodium bicarbonate, or an equivalent proportion of magnesium bicarbonate or ammonium bicarbonate, together with a suitable solvent liquid (alcohol, ether, acetone). The resulting paste is rolled into the form of a sheet or the like, on the face or faces of which incisions are made, after which the sheet is subjected to a second rolling to reduce its thickness.—A. S.

Explosives. Anglo-French F. and S. Ltd., and J. B. Edwards, London. Eng. Pat. 12,188, June 4, 1908. Addition to Eng. Pat. 24,025 of 1907. (See preceding abstract.)

To prevent the production of flame during combustion, the addition to explosives of alkaline salts in the form of a paste has been suggested. But such salts may deliquesce and thus affect the stability of the explosive, and it is for the purpose of overcoming this difficulty and avoiding such liability that the present patent is taken out. According to this improvement, the explosive is mixed with beeswax (5 per cent.), sodium bicarbonate (2 per cent.), and benzine (5 per cent.). The beeswax has the effect of coating the particles of sodium bicarbonate, thus protecting them from air and moisture, whilst the benzine on decomposing during explosion, liberates hydrogen, which uniting with the oxygen of the air, forms water vapour, which again serves to extinguish flame or flash. The paste described, is subjected to the shaping process mentioned in the main patent.

XXIII.—ANALYTICAL CHEMISTRY.

APPARATUS.

PATENTS.

Photometer. W. Fennell, Wednesbury, and W. P. Perry, Tipton, Staffs. Eng. Pat. 6971, March 30, 1908.

THE patent relates to improved forms of flicker photometers. In one form (see figs.), a rotating disc is employed, consisting of two wedge-shaped parts, *a*, *b*, of translucent material, insulated from each other by an opaque film, *c*, and each illuminated by a source of light, *A*, and *B*, respectively, on its side and observed on edge through the eye-piece, *d*. In another form a single rotating translucent disc, with parallel sides covered with opaque films, is employed, the films being cut away alternately on either side of the disc, so that no section of the latter

is covered by more than one film. In a third modification a stationary piece of translucent material is mounted between two opaque rotating discs, each cut away so as to allow the light to pass through for alternate periods from the two sides. As translucent material paraffin wax protected by thin sheets of glass or mica, or glass vessels filled with a translucent liquid may be employed. An improved sighting arrangement is also described.

—A. S.

Fluids: Process and apparatus for the examination of —. H. B. Bishop, Fr. Pat. 394,107, Sept. 10, 1908.

THE patent relates to means for determining variations in the concentration of solutions or in the composition of fluid mixtures, by measuring the electric conductivity of such solutions or mixtures. The process consists essentially of a comparison of the conductivity of the substance under examination with that of a standard composed of the same substance. The effect of variations of temperature is thus avoided as the contents of both the standard tube and the "testing tube" are subject to such variations. The difference of electric conductivity of the standard material and the material under examination is observed by means of a device similar to a Wheatstone bridge.—A. S.

INORGANIC—QUANTITATIVE.

Cobalt: Determination of — by means of potassium nitrite. L. L. de Koninck, Bull. Soc. Chim. Belg., 1909, 23, 11—13.

THE precipitation of cobalt as potassium cobaltinitrite is best effected in the presence of free nitric acid, employing a large excess of potassium nitrite. For example, the addition of 15 c.c. of 5*N* potassium nitrite solution to 5 c.c. of *N*/₂ cobalt nitrate, acidified with 2 c.c. of 6*N* nitric acid, ensures complete precipitation of the cobalt, and the precipitate has the bright yellow colour of the pure cobaltinitrite.—F. SONN.

Pyridine in ammonia. Pinchbeck. See VII.

ORGANIC—QUALITATIVE.

Dyestuffs on dyed cotton. Holden. See V.

Olive oil and Baudouin's reaction. Zega and Todorovic. See XII.

Purity of lactose. Hillringhaus and Heilmann. See XVI.

Reaction of α -naphthol. Dané. See XX.

Dihydroxyacetone reactions. Denigés. See XX.

ORGANIC—QUANTITATIVE.

Carbon tetrachloride for fat determination. Rammstedt. See XII.

Theobromine in cocoa. Kreutz. See XVIII.

XXIV.—SCIENTIFIC & TECHNICAL NOTES.

Oxydases and peroxydases, Artificial —. Martinand. Compt. rend., 1909, 148, 182—183.

THE oxides of the alkali and alkaline-earth metals which can form peroxides, fix atmospheric oxygen in an active form, and produce substances resembling organic oxydases; the same is the case with the most highly oxidised salts of metals forming several oxides. These substances may be looked upon as formed of a peroxydase (the salt itself) and an oxygenase (the peroxide formed by action of air on the salt). This inorganic oxygenase can be replaced, as in organic oxydases, by hydrogen peroxide. In other respects also, these substances closely

resemble organic oxydases. These properties of alkali and alkaline-earth compounds, and of ferric chloride, are of interest in their bearing on the oxidation phenomena of animal and vegetable life.—J. T. D.

The Imperial Institute. Board of Trade J., Feb. 11, 1909. [T.R.]

DURING the last quarter of 1908, the Scientific and Technical Department of the Imperial Institute received 80 requests for investigation and despatched 114 reports during the quarter, the totals for the year 1908 being respectively 375 and 393. At the beginning of the present year 141 investigations were in progress. Rhodesian magnesite, African wild silks, West African and Indian oil-seeds, Bermuda tobacco, and a new West African rubber plant were amongst the substances more recently investigated, and assistance had been rendered in connection with the development of the flax industry in St. Helena. New colonial exhibits had been transferred from the Franco-British Exhibition to the Exhibition Galleries of the Institute. These exhibits came from many parts of the British Empire, including Australia, Canada, India, Natal, New Zealand, and West Africa.

The galleries were visited by 29,427 persons during the quarter, bringing the total for the year 1908 up to 110,189.

New Books.

LABORATORIUMSBUCH FÜR DIE ERDÖL-INDUSTRIE. Eine gedrängte Schilderung der wichtigeren in der Praxis des Erdölchemikers vorkommenden Untersuchungsmethoden. Von Dr. Richard Kissling. Wilhelm Knapp's Verlag, Halle a. S. 1908. Price M3-00.

8vo volume, containing 82 pages of subject matter with 22 illustrations. The book forms Bd. V of a series of "Laboratoriumsbücher für die chemischen und verwandten Industrien." The subject matter is arranged as follows: I. The more important methods of investigation. II. Examination of petroleum, and the products of the petroleum industry. III. Definition of chemical engineering management. IV. Examination of the individual products employed in the industry.

LABORATORIUMSBUCH FÜR DIE BRAUNKOHLENTEER-INDUSTRIE. Braunkohlengruben, Braunkohlenteerschwefelereien und Destillationen, Paraffin und Kerzenfabriken, sowie Oelgasanstalten. Von Dr. Ed. GRAEFE. Wilhelm Knapp's Verlag, Halle a. S. 1908. Price M. 6-60.

FORMS Bd. VI. of the series of "Laboratoriumsbücher," above referred to. 8vo. volume, containing 176 pages of subject matter with 65 illustrations, and alphabetical indexes of subjects and authors' names. The subject matter is classified and arranged under the following heads: I. Analysis of coals. II. Examination of the products: (i.) Tar. (ii.) Cokes. (iii.) Gaseous products. (v.) Aqueous products. III. Examination of the products of tar distillation. IV. Examination of the residues of the mixing processes. V. Crude paraffin and shale. VI. Examination of the materials for treating the products in the refining of paraffin. VII. Examining prepared paraffin wax. VIII. The various stages of the candle-moulding process. IX. Testing the oils. X. Special investigations of the oils. XI. Examining some by-products of the brown coal-tar distillation, and of the materials employed. XII. Analysis of the brown coal bitumen (montan wax). XIII. Examination of asphaltic oils and oil-gas.

LE LACK UND FERNISFABRIKATION. Von Professor MAX BOTTLE. Wilhelm Knapp's Verlag, Halle a. S. 1908. Price M. 4-50.

It forms Bd. XVI of the "Monographien über chemisch-technische Fabrikationsmethoden." It is an 8vo.

volume containing 122 pages of subject matter, with 29 illustrations, a list of works of reference in connection with the main topic, and indexes of subjects and names of authors. The arrangement of the text is planned as follows: I. Introductory and historical. II. Distinguishing varnishes. III. Raw materials for the varnish manufacture. IV. Preparation and general work. V. Turpentine, benzene, and petroleum spirit varnishes. (i.) Oil of turpentine varnishes. (ii.) Benzene varnishes. (iii.) Asphaltum varnishes. (iv.) Caoutchouc varnishes. VII. Alcoholic and other volatile and non-volatile varnishes. VIII. Colouring, decolorising, and filtering varnishes. IX. Preparation of printing and lithographic varnishes, soap-varnishes, resin, and casein varnishes.

RAPID METHODS FOR THE CHEMICAL ANALYSIS OF SPECIAL STEELS, STEEL-MAKING ALLOYS, AND GRAPHITE. By CHAS. M. JOHNSON, Chief Chemist to the Park Steel Works of the Crucible Steel Co. of America. John Wiley & Sons, New York. Chapman and Hall, Ltd. 1909. Price 12s. 6d.

SMALL 8vo. volume, containing 217 pages of subject matter, with 12 illustrations, and an alphabetical index. The methods described are as follows: I. Qualitative tests for chromium, vanadium, copper, titanium, nickel, molybdenum, and tungsten in steel. II. Analyses of: vanadium steel and ferro-vanadium; of titanium steel and ferro-titanium; of tungsten powders; of tungsten steel and chrome-tungsten steel; of low per cent. tungsten-steel; of molybdenum powders; of tungsten-molybdenum steels, and of ferro-chrome, chrome ore and carbonless chrome. VII. Determinations of: aluminium in steel, and of copper in steel and pig iron. VIII. Separation of nickel and copper from iron and vanadium by potassium ferrieyanide. IX. Determination of copper in metallic copper. X. Rapid determination of nickel in the presence of chromium, iron and manganese. XI. Analysis of ferromanganese. XII. Rapid volumetric method for manganese in the presence of iron, calcium, and magnesium. XIII. Determinations of carbon in iron and steel by direct ignition with red lead or litharge, and of carbon in steel, ferro-alloys, and plumbago, by means of an electric combustion furnace, &c. XIV. Carbon in steel by colour. XV. Phosphorus in steel, pig-iron, bar iron, and wash metal. XVI. Sulphur in steel, bar iron, pig iron, and wash metal. XVII. Manganese in special steels, &c. XVIII. Silicon in iron and steel. XIX. Analysis of graphite and graphite crucibles. XX. Annealing steel. XXI. Simple method for making clay combustion boats.

INTRODUCTION TO THE SCIENCE OF RADIO-ACTIVITY. By CHARLES W. RAFFETY. Longmans, Green, and Co., 39, Paternoster Row, London, 1909. Price 4s. 6d. New York, Bombay, and Calcutta.

8vo. volume containing 201 pages of subject matter, with 27 illustrations, and an alphabetical index. The subject matter is classified and arranged as follows: PART I. (i.) Spectrum of radium, &c. (ii.) Rays emitted by radium; their nature, &c. (iii.) Methods of investigation. (iv.) The α rays, &c. The β rays. Photographic action, &c. (v.) The γ rays; and secondary radiation, &c. PART II. (i.) Radio-active products. Thorium X, and Uranium X. (ii.) Radium emanation. (iii.) Theoretical considerations. (iv.) Atomic structure. Electron theory of the atom. (v.) Electron theory and the rays of the radio-active elements, &c. (vi.) Radio-active transformations of thorium. Thorium emanation. (vii.) Origin of radium. Uranium in relation to radium. PART III. (i.) Kathode, canal and X rays. Magnetic deflections, &c. (ii.) Electroscopes, &c.

THE THEORY OF VALENCY. By J. NEWTON FRIEND, Ph.D., M.Sc. Longmans, Green & Co., 39, Paternoster Row, London, 1909. Price 5s. New York, Bombay, and Calcutta.

ONE of the series of text books of Physical Chemistry edited by Sir William Ramsay, K.C.B., F.R.S. Small 8vo. volume, containing 169 pages of subject matter, with 6 illustrations, and alphabetical index of names and subjects. The text is classified as follows: I. Lavoisier,

Dalton, and Berzelius. II. Early theories of Chemical combination. III. Theory of valency. IV. Valency and the periodic law. V. Exceptions to the periodic law. VI. Valency of carbon. VII. Thiele's theory. VIII. Valency of the elements of groups O, I, II, III, and IV. IX. Valency of nitrogen. X. Valency of the elements of groups V, VI, VII, and VIII. XI. Werner's theory. XII. Electrochemical theories. XIII. Physical cause and nature of valency.

OUTLINES OF PHYSICAL CHEMISTRY. By GEORGE SENTER, Ph.D., Lecturer on Chemistry at St. Mary's Hospital, &c. Methuen & Co., 35, Essex Street, London, W.C. 1909. Price 3s. 6d.

SMALL 8vo. volume, containing 366 pages of subject matter, with 39 illustrations, and an alphabetical index. The text is classified and arranged under the following heads: I. Fundamental principles of chemistry. The atomic theory. II. Gases. III. Liquids. IV. Solutions. V. Dilute solutions. VI. Thermochemistry. VII. Equilibrium in homogeneous systems, &c. VIII. Heterogeneous equilibrium. The phase rule. IX. Velocity of reaction. Catalysis. X. Electrical conductivity. XI. Equilibrium in electrolytes. Strengths of acids and bases. Hydrolysis. XII. Theories of solution. XIII. Electromotive force.

STATISTICAL ABSTRACT FOR THE BRITISH EMPIRE IN EACH YEAR FROM 1893 TO 1907. FIFTH NUMBER. [Cd. 4486.] Wyman and Sons, Fetter Lane, E.C. Price 1s. 2d.

This publication contains statistics of the area, population, and trade of each portion of the Empire with foreign countries and with other portions of the Empire, figures as to shipping, and statements as to the production and consumption of staple articles in the various countries of the Empire.

BULLETIN OF THE IMPERIAL INSTITUTE. Vol. VI., No. 4. Price 1s.

This issue of the Bulletin contains accounts of recent investigations made in the Scientific and Technical Department of the Imperial Institute regarding some African oils and oil seeds, rapia wax, cotton from British Guiana, fibres from Fiji, and "Bitinga" rubber, together with general notices respecting a number of economic products and their development.

FOREIGN IMPORT DUTIES, 1908. STATEMENT OF THE RATES OF IMPORT DUTIES LEVIED IN EUROPEAN COUNTRIES, EGYPT, THE UNITED STATES, MEXICO, ARGENTINA, JAPAN, CHINA AND PERSIA UPON THE PRODUCE AND MANUFACTURES OF THE UNITED KINGDOM. [Cd. 4414.] Wyman and Sons, Fetter Lane, London, E.C. Price 3s. 8d.

Patent List.

Where a Complete Specification accompanies an Application, an asterisk is affixed. The dates given are (i) in the case of Applications for Patents, the dates of Application, and (ii) in the case of Complete Specifications Accepted, those of the Official Journals in which acceptances of the Complete Specifications are advertised.

Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

I.—PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

2400. Crépelle-Fontaine. Obtaining and recovering alcohol and other in various industries. Feb. 1.
2485. Hampson. Diffusion processes for separating gases of different densities. Feb. 2.
2531. Black and Lennox. Continuous drying machines. [Addition to No. 12,087 of 1907.] Feb. 2.

2544. Baxter. Machines for separating solids of different densities. Feb. 2.

2643. Hemming. Cleansing solid and liquid materials and freeing them from gas. [Fr. Appl., Feb. 3, 1908.]* Feb. 3.

3302. Ilges. Process and apparatus for rectifying liquids. [Ger. Appl., Feb. 12, 1908.]* Feb. 10.

3394. Bartelt. Apparatus for liberating gases from bodies containing them. Feb. 11.

3432. Greville. Drying machines. Feb. 11.

3477. Andrews. Stills for distilling ammoniacal and other liquids. Feb. 12.

3493. Cochrane. *See under XIII.C.*

COMPLETE SPECIFICATIONS ACCEPTED.

2613 (1908). Jacob, Alexander, and Serenyi. Devices for introducing air, steam, or other gases into liquids. Feb. 10.

2815 (1908). Ogle (Cockburn). Apparatus for removing liquid from solid materials. Feb. 17.

2914 (1908). Arndt. Air pyrometers. Feb. 17.

3394 (1908). Boulé (Schmatolla). Reverberatory and like furnaces. Feb. 17.

4123 (1908). Wilson. Firing rotary or like kilns or furnaces. Feb. 17.

20,972 (1908). Maschinenfabrik Grevenbroich. Evaporating apparatus. Feb. 10.

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

2313 and 2314. Fischer. Mantles for incandescent gas lamps. Feb. 1.

2389. British Thomson-Houston Co. (General Electric Co.). Treatment of electric lamp filaments. Feb. 1.

2449. Schramm and Kershaw. *See under XIII.A.*

2620. Key. Production of gas for illuminating or heating. Feb. 3.

2813. Williams. *See under VII.*

2853. Siemens and Halske A.-G. Manufacture of electric incandescence filaments from tungsten, &c. [Ger. Appl., Feb. 11, 1908. Addition to No. 4814 of 1908.]* Feb. 5.

3003. Parker. Vertical retorts for the destructive distillation of coal. Feb. 8.

3171. Larbeck. Catalytic material for automatic ignition of illuminating gas. [Fr. Appl., March 5, 1908.]* Feb. 9.

3230. Hornett. Preparation for producing greater radiant heat from coal or coke. Feb. 10.

COMPLETE SPECIFICATIONS ACCEPTED.

2655 (1908). Vivian, Davies, and Grote. Manufacture of artificial fuel. Feb. 10.

6347 (1908). Vignon. Apparatus for making hydrogen for lighting, heating, &c. Feb. 10.

10,590 (1908). British Thomson-Houston Co. (General Electric Co.). Electric incandescence lamp filaments. Feb. 10.

14,692 (1908). Bethge. Mixture for flash lights, &c. Feb. 17.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, PETROLEUM, AND MINERAL WAXES.

APPLICATIONS.

2873. Marriott. Treatment of natural pitch, asphalt, or bitumen. Feb. 6.

3074. Spengler. Purification of tar, tar oils, pine oils, and other distillation products.* Feb. 8.

IV.—COLOURING MATTERS AND DYESTUFFS.

APPLICATIONS.

2373. Newton (Bayer and Co.). Manufacture of anthracene derivatives. Feb. 6.

2386. Johnson (Badische Anilin und Soda Fabrik). Manufacture of halogenated indigo. Feb. 1.

2608. Bloxam (Act. Ges. f. Anilinfabr.). Manufacture of a monoazo dyestuff especially adapted for making lakes. Feb. 3.

2609. Imray (Meister, Lucius, und Brüning). Manufacture of greenish-blue hexahalogenindigos. Feb. 3.
 2702. Newton (Bayer und Co.). Manufacture of anthracene derivatives. Feb. 4.
 2918. Haas. Derivatives of carbazol and dyestuffs therefrom. [Fr. Appl., May 15, 1908.]* Feb. 6.
 3019. Imray (Meister, Lucius, und Brüning). Manufacture of penta- and hexa-halogenised indigos. [Addition to No. 13,789 of 1908.] Feb. 8.
 3276. Newton (Bayer und Co.). Manufacture of anthracene dyestuffs. Feb. 10.
 3292. Ransford (Cassella und Co.). Manufacture of indigo sulphides and their halogen compounds. Feb. 10.
 3543. Smiles and Barnett. Blue sulphur dyestuff. Feb. 13.
 3602. Meister, Lucius, und Brüning. Manufacture of new dyestuffs. [Ger. Appl., March 28, 1908.]* Feb. 13.

COMPLETE SPECIFICATIONS ACCEPTED.

- 2721 (1908). Ransford (Cassella und Co.). Manufacture of azo dyestuffs. Feb. 10.
 3373 (1908). Ellis (Chem. Fabr. vorm. Sandoz). Manufacture of yellow dyes for wool. Feb. 10.
 10,412 (1908). Johnson (Badische Anilin und Soda Fabrik). Manufacture of compounds and colouring matters of the anthracene series. Feb. 17.
 16,372 (1908). Merz. Preparation of a monoazo dye-stuff especially suitable for use as a blue-red pigment colour. Feb. 17.
 28,272 (1908). Johnson (Badische Anilin und Soda Fabrik). Manufacture of azo colouring matter. Feb. 17.

V.—PREPARING, BLEACHING, DYEING, PRINTING, AND FINISHING TEXTILES, YARNS, AND FIBRES.

APPLICATIONS.

2437. Calico Printers' Assoc., and Davis. Calico printing. Feb. 2.
 2522. Johnson (Badische Anilin und Soda Fabrik). *See under XIV.*
 2782. Sutherland. Degumming or cleansing and strengthening stalk fibres. Feb. 5.
 3055. Newton (Bayer und Co.). Process of dyeing and printing. Feb. 8.
 3087. Holden. Preventing tendering of cotton goods that have been dyed with sulphide colours. Feb. 9.
 3196. Bouchat. Apparatus for removing grease from and bleaching wool.* Feb. 9.
 3200. Dassonville. Electrolytically cleaning or bleaching animal or vegetable fibres, tissues, &c.* Feb. 9.
 3356. Bromley. Material for filling cotton, linen, or other fabrics. Feb. 11.
 3521. King. Treatment of fibres. Feb. 12.

COMPLETE SPECIFICATION ACCEPTED.

- 10,951 (1908). Shuman and Shuman. Apparatus for cleansing wool. Feb. 10.

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

2521. Johnson (Badische Anilin und Soda Fabrik). Manufacture of stable hydrosulphites and mixtures containing them. Feb. 2.
 2523. Johnson (Chem. Fabr. Griesheim-Elektron). Removing carbon dioxide from gases and replacing it by hydrogen, and preparation of pure hydrogen. Feb. 2.
 2524. Johnson (Chem. Fabr. Griesheim-Elektron). Removal of arsenic from dilute sulphuric acid. Feb. 2.
 2525. Johnson (Badische Anilin und Soda Fabrik). Manufacture of ammonia. [Comprised in No. 2414, Feb. 1908.] Feb. 3.
 2548. Bell. Purification of brine. Feb. 4.
 2813. Williams. Treatment of burnt spent oxide. Feb. 5.
 3036. Wilton and Wilton. Saturators for making sulphate of ammonia. Feb. 8.
 3061. Feld. Extraction of sulphuretted hydrogen and sulphur dioxide from gases and the obtainment of sulphur. Feb. 8.

3188. Johnson (Chem. Fabr. Griesheim-Elektron). Preparation of pure hydrogen. Feb. 9.
 3189. Peniakoff. Manufacture of sodium sulphate or other alkali sulphate. [Fr. Appl., Jan. 29, 1908.]* Feb. 9.
 3395. Bartelt. Production of chlorine. Feb. 11.
 3477. Andrews. *See under I.*
 3592. Taussig. *See under XI.*
 3622. Taussig. *See under XIX.*

COMPLETE SPECIFICATIONS ACCEPTED.

- 2414 (1908). Johnson (Badische Anilin und Soda Fabrik). Manufacture of ammonia. Feb. 10.
 6347 (1908). Vignon. *See under II.*
 9003 (1908). Price. Manufacture of compounds containing sulphur. Feb. 10.
 2525 (1909). Johnson (Badische Anilin und Soda Fabrik). Manufacture of ammonia. Feb. 10.

VIII.—GLASS, POTTERY, AND ENAMELS.

APPLICATIONS.

2490. Bloxam (Hoorickx and Hindel). Manufacture of silvered glass mirrors.* Feb. 2.
 3546. Brightmore. New abrasive material.* Feb. 13.
 2231 (1908). Vincart-Mouzin. Tunnel kiln for baking pottery, &c. Feb. 10.
 22,613 (1908). Grunzweig und Hartmann Ges. Manufacture of porous ceramic articles. Feb. 10.
 23,461 (1908). Berdel. Manufacture of porcelain or china-ware of low fusing grade. Feb. 17.

COMPLETE SPECIFICATIONS ACCEPTED.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

2534. Mueller. Impregnating wood. [Swed. Appl., Feb. 15, 1908.]* Feb. 2.
 2599. Smidth and Co. Treatment of stony and earthy materials particularly for making cement. [Ger. Appl., Feb. 27, 1908.]* Feb. 3.
 2849. Pyrotrass Soc. Anon. Granulating slag. [Fr. Appl., Feb. 13, 1908.]* Feb. 5.
 3425. Lion. Burning cement in shaft kilns with fuel waste and an oxidising blast.* Feb. 11.
 3426. Lion. Reducing expenditure on fuel in burning Portland cement.* Feb. 11.

COMPLETE SPECIFICATIONS ACCEPTED.

- 6538 (1908). Brincker. Colouring and impregnating wood. Feb. 10.
 18,738 (1908). Allan. Manufacture of clinker for making Portland cement. Feb. 10.

X.—METALS AND METALLURGY.

APPLICATIONS.

2359. Greenway, Sulman, and Higgins. Concentration of ores. Feb. 1.
 2725. Mallmann. Crucible furnaces. Feb. 4.
 2843 and 2844. British Thomson-Houston Co. (General Electric Co.). Plating metals.* Feb. 5.
 2938. Sebillot. Recovery of metalliferous fumes obtained in roasting or smelting ores. [Fr. Appl., Feb. 7, 1908.]* Feb. 6.
 3134. Harden, and Amalgaine, Ltd. Metallic flux for joining metals. Feb. 9.
 3604. Sang. Coating metal surfaces with other metals.* Feb. 13.
 3623. Vautin. Utilisation of heat contained in slags. Feb. 13.

COMPLETE SPECIFICATIONS ACCEPTED.

- 4644 (1908). British Thomson-Houston Co. (General Electric Co.). Reduction of metallic compounds and furnaces therefor. Feb. 10.
 5198 (1908). Miele. Producing a uniform metallic coating on metal articles. Feb. 17.
 6561 (1908). Pritchard, and United Alkali Co. Apparatus for producing iron from finely-divided ores. Feb. 10.

11,008 (1908). Rayner (Innes, Procter, and Hayles). Apparatus for separating cyanide, alkaline, and other solutions from slimes, sand, &c. Feb. 17.

11,259 (1908). Lee. Reverberatory smelting furnaces. Feb. 17.

16,807 (1908). Marks (Soc. Anon. Ital. Armstrong & Co.). Furnaces for the cementation of articles of iron, steel, and steel alloys. Feb. 17.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

APPLICATIONS.

2365. Greil. *See under XXIII.*

2641. Marino. Treatment of wood for use in secondary batteries.* Feb. 3.

2683. Marino. Secondary or storage batteries.* Feb. 4.

3200. Dassonville. *See under V.*

3592. Taussig. Electrolysis of alkali chlorides or the like. Feb. 13.

3599. Grunwald. Electrical induction furnaces. [Ger. Appl., May 7, 1908.]* Feb. 13.

3626. Cowper-Coles. Electrodeposition of metals. Feb. 13.

COMPLETE SPECIFICATION ACCEPTED.

3160 (1908). Cowper-Coles. Cathodes for use in electro-deposition of iron and other metals. Feb. 17.

XII.—FATTY OILS, FATS, WAXES, AND SOAPS.

APPLICATION.

3076. Frestadius. Extraction or separation of oils. Feb. 8.

COMPLETE SPECIFICATIONS ACCEPTED.

10,277 (1908). Doull. Filtering oils, fats, waxes, and their products. Feb. 17.

17,670 (1908). Van der Lande. Oil decolouring, bleaching, and thickening apparatus. Feb. 10.

XIII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, &c.

(A.)—PIGMENTS, PAINTS.

APPLICATIONS.

2449. Schramm and Kershaw. Manufacture of carbon black. Feb. 2.

2487. Waterlow Bros. and Layton, Ltd., Harrison, and Brearley. Ink for printing bankers' cheques, &c. Feb. 2.

3595. Child and Johnston. Manufacture of printing and lithographic inks. Feb. 13.

COMPLETE SPECIFICATION ACCEPTED.

16,372 (1908). Merz. *See under IV.*

(B.)—RESINS, VARNISHES.

APPLICATION.

3074. Sprenger. *See under III.*

COMPLETE SPECIFICATION ACCEPTED.

19,833 (1908). Pellnitz. Manufacture of resinous turpentine oil from pine oil. Feb. 17.

(C.)—INDIA-RUBBER.

APPLICATIONS.

2624. Wallace. *See under XX.*

3493. Cochrane. Drying rubber and other substances. Feb. 12.

COMPLETE SPECIFICATION ACCEPTED.

2787 (1908). Norzagaray. Treatment of rubber. Feb. 17.

XIV.—TANNING, LEATHER, GLUE, SIZE, &c.

APPLICATIONS.

2504. Mackay. Leather product.* Feb. 2.

2522. Johnson (Badische Anilin und Soda Fabrik). Bleaching agent and its use for bleaching leather, glue, feathers, and straw.* Feb. 2.

XVI.—SUGAR, STARCH, GUM, &c.

COMPLETE SPECIFICATION ACCEPTED.

19,726 (1908). Klopfer. *See under XVIII.A.*

XVII.—BREWING, WINES, SPIRITS, &c.

COMPLETE SPECIFICATION ACCEPTED.

3166 (1908). Humphrey. Desiccating yeast. Feb. 10.

XVIII.—FOODS; SANITATION, WATER PURIFICATION; AND DISINFECTANTS.

(A.)—FOODS.

APPLICATIONS.

2682. Kuniek. Preservation of milk without preservatives. Feb. 4.

2995. Yeo, Hall, and Goskar. Aeration of liquids and manufacture of mineral waters. Feb. 8.

DR. E. KNECHT IN THE CHAIR.

THE CONSTANTS OF JASMINE FLOWER WAX.

BY L. G. RADCLIFFE AND J. ALLAN.

Of recent years a solvent process has been adopted at Grasse and elsewhere for obtaining the odoriferous constituents of flowers. In the case of jasmine the petals alone are extracted with a low boiling petroleum ether; the resulting solution contains the odoriferous constituents mixed with a large proportion of a wax-like substance. This petroleum ether extract on evaporation at a low temperature yields a highly odorous mass and this is designated as "Essence naturelle concrete de jasmin." In order to prepare a floral extract suitable for use in perfumery this material is macerated with strong alcohol and the mixture, after having been chilled to about -10°C . is filtered; the residue left after filtration is only faintly odorous, and is usually highly coloured, and to distinguish it the authors have named this residue *jasmine-flower wax*.

The investigation of this wax and others of floral origin appears to be of considerable interest, especially when the data obtained are compared with those given by beeswax, and the authors have in hand the examination of several of these waxes and fully realise the incompleteness of the present communication, which is due to lack of material.

The sample was a hard, yellowish-brown substance, having but a slight odour of jasmine. Since the wax was found to contain a little alcohol this was removed by keeping the wax molten until no frothing was visible, after which it was used for the following examination:—

The solidifying point, as in the titer test, was between 60° and 57°C . The examination with the Zeiss butyrorefractometer was a little difficult on account of the high melting-point of the wax, but the following figures were obtained:—

The scale reading at 84°C . was 30; 74° , 33; 70° , 36; 57° , 38; 62° , 40; 60° , 42; 56° , 44.

It is interesting to note that Leikowitsch gives for beeswax at 62°C . the reading 29.5 to 30. The acid value as determined on 5 grms. of wax dissolved in a mixture of neutral alcohol and ether; it corresponded to 2.8 grms. of potassium hydroxide for one gm. of wax.

The wax was difficult to saponify, and the saponification value was determined by dissolving the substance in neutral amyl alcohol, adding alcoholic potash as usual, and boiling for five hours on a sandbath; the final result was that 65.8 mgrms. of potassium hydroxide were required per gm. of wax. Using sodium ethylate for the saponification, the figure was 63 mgrms. The use of amyl alcohol as a solvent for difficultly saponifiable waxes greatly facilitates the reaction. The iodine value of the wax by "Ijs" method was from 52 to 53 per cent.

The fatty acids were isolated from the saponified residues in the following manner:—The residues were boiled with a large volume of water until all the alcohol was expelled, when the unsaponifiable matter separated out as a white scum; this was skimmed off as completely as possible, and was proved not to be an insoluble soap by its solubility in ether, its low melting point, and the fact that it left no residue on ignition. Subsequent experiments showed that it was very difficult to remove the whole of the unsaponifiable matter from the fatty acids which were precipitated on acidifying the soapy liquor; however, by

repeatedly dissolving the fatty acids in alkali, extracting with petroleum ether, and reprecipitating with a mineral acid, a hard white mass was obtained having a mean molecular weight of 398 and an iodine absorption of 39 per cent. It was not found practicable to obtain sufficient of these fatty acids to enable the titer test to be done, but when recrystallised from boiling alcohol the mixed acids melted slowly between 57° and 65°C . The unsaponifiable matter yielded a mass of well crystallised white needles, from ether, having a sharp melting point of 64°C .; on heating this unsaponifiable matter with soda-lime, hydrogen was evolved, indicating the presence of alcohols, but attempts to prepare acetyl derivatives were not very successful, though ultimately a substance was obtained melting at 45°C .; however the amount was too small for an analysis to be made.

In conclusion, we desire to thank Mr. Batey for his assistance in carrying out some of the above experiments.

DISCUSSION.

The CHAIRMAN believed this was the first time that the wax obtained from the flowers of an individual plant had been isolated and described, and the data appeared to indicate that this wax was not identical with beeswax.

Mr. J. H. ROSEASON mentioned that the process described was essentially similar to that recommended by Dragendorff, in his "Plant Analysis," 40 years ago, and said it was strange that so late as the present day this laboratory process had become a commercial one.

Mr. TERLESKY believed some of the fine odours in flowers were to-day being distilled by steam.

Mr. J. W. YOUNG asked if the scent prepared from the concretes ultimately resembled that of the flowers?

Mr. COLEMAN drew the authors' attention to the chlorine compounds known as "Vitran." They were coming into use for solvent purposes.

Mr. J. H. LESTER said there was obviously a difference between the jasmine wax and beeswax. So far as he remembered there was no great difficulty in the use of an autoclave at a very low pressure for purposes of saponification, but it necessitated the use of caustic-resisting vessels within the outer metallic vessel.

Mr. JOHN ALLAN said Dr. Knecht had suggested it was possible the extraction with alcohol in the first place might account for the low acid value of the jasmine wax. He thought it was extremely unlikely, because the acids which existed in these waxes were not easily soluble in alcohol, and their solubility was decreased enormously at the temperature to which the alcoholic extract was reduced before the waxes were filtered off. So small was the solubility that when one concentrated the alcoholic extracts in vacuum, as was done for the purpose of preparing the highly concentrated "concrete" essence, one obtained a substance which was certainly somewhat viscid, but perfectly fluid, and only very slightly acid. This would seem to do entirely away with the possibility of the free acid being dissolved from the wax during the alcoholic extraction. By distillation in steam it was quite possible to obtain a floral odour from one flower which would be satisfactory, and to find that a perfume or perfumed oil obtained in the same way from another flower was unsatisfactory, as the various esters in essential oils were hydrolysed to different extents under the same conditions. It was quite right that concrete scents were not absolutely true to type. The mere fact that for the purpose of distilling off the petroleum ether the material had to be subjected to heat was sufficient to alter the character of the odour. The scents obtained by the process indicated in the paper were distinctly truer as a type than those obtained by any distillation process previously employed. The autoclave could be used in the laboratory for saponifying waxes, but an ordinary flask or condenser would do as well.

EFFECT OF ADDITION OF SALT TO THE CAUSTIC SODA LYE USED IN MERCERISING.

BY JULIUS HÜBNER, M.Sc. TECH., F.I.C.

Hübner and Pope demonstrated in a paper read before this Society (Vol. 23, 1904, p. 404) that the production of the lustre during mercerisation of cotton yarn and cloth depends upon three factors, namely, the shrinking, the swelling, and the untwisting of the individual cotton fibres: they showed further that the degree of lustre produced is considerably influenced by the addition of sodium silicate or glycerin to the soda lye used in the mercerisation. W. Vieweg (Ber., 1908, 3269) concludes that cotton takes up considerably more sodium hydroxide from a soda lye which has been saturated with sodium chloride than from a lye of the same concentration containing no salt. O. K. Miller (J. Russ. Chem. Phys. Ges., 1905, 361), on the other hand, states that the absorption of sodium hydroxide by cellulose from caustic lyes is not influenced by the presence of carbonates or chlorides of the alkalis. It is indicated in Vieweg's tables that 100 grms. of cotton when immersed in a soda lye containing 12 per cent. of sodium hydroxide absorbs 8.4 grms. of sodium hydroxide, whilst it is capable of taking up 14.5 grms. of sodium hydroxide from a 12 per cent. lye which has been saturated with salt: further from a 20 per cent. lye the same amount of cotton absorbs 13.2 grms. of sodium hydroxide and 17.4 grms. of sodium hydroxide if this lye is saturated with sodium chloride. In view of these contradictory statements it seemed desirable to carry out a series of determinations under similarly exact conditions to those previously described in order to ascertain definitely whether soda lye saturated with salt actually exerts a greater mercerising action than the ordinary lye used at present in technical mercerisation. For this purpose a number of comparative experiments were carried out with cotton hanks on a hank mercerising machine, under identical conditions.

For the purpose of determining the degree of shrinkage which takes place if the hanks are treated with the caustic lye, without the application of tension, a number of hanks measuring 420 yards each were reeled. These hanks were immersed in soda lye containing 12 per cent. and 20 per cent. of sodium hydroxide respectively, with and without the addition of salt. In the preparation of the caustic soda lyes and the saturation of the same with salt, the method described by Vieweg (*loc. cit.*) was carefully followed. After immersion the hanks were washed until free from soda, dried and re-measured with the following results:—

	Shrinkage, per cent.
Soda lye, 12 per cent. sodium hydroxide	11.5
" " " saturated with salt	6.8
" " 20 per cent. sodium hydroxide	18.6
" " " saturated with salt	15.7

The shrinkage of the hanks treated with the soda lyes saturated with salt is, therefore, considerably less than is the case in mercerising with ordinary soda lye.

On dyeing the hanks treated as described above it was found that the affinity of the cotton fibres for the substantive cotton colours is considerably lessened by saturating the mercerising soda lye with salt.

On investigating under the microscope the action upon cotton fibres of the different soda lyes used in the experiments it was found that the untwisting of the individual fibres proceeds much more slowly and much less completely with lyes to which salt had been added.

After those observations had been made it only remained to be determined whether, in accordance with the observations of Hübner and Pope (*loc. cit.*), the degree of lustre produced on the fibres would be diminished by the addition of an agent (salt in this instance) which retards one or more of the typical actions, namely, shrinking, untwisting and swelling of the fibres, to the caustic soda solution used in mercerising under tension.

With this object hanks were mercerised with the different solutions, under tension, on the hank mercerising machine: the comparison of the different hanks, before and after dyeing with substantive cotton colours, showed that the lustre suffers very distinctly from the saturation of the soda lye with salt.

It seemed of interest to ascertain how cotton which has been mercerised under the conditions described above would behave towards the zinc-chloride iodine solution (Hübner, this Journal, 1908, 27, 105) which has been shown to afford a definite means of distinguishing mercerised from non-mercerised cotton. It was found in every case that the blue coloration produced by the reagent was distinctly lighter when the soda lye used in the mercerisation was saturated with salt. This is of importance bearing upon the utility of the reagent for the purpose of ascertaining the degree of mercerisation, because it proves that the depth of the blue coloration of mercerised cotton produced by the application of this reagent indicates clearly the degree of mercerisation in so far as this proceeds parallel with the shrinkage, the affinity for the substantive cotton colours, the untwisting of the fibres and with the degree of lustre which is the ultimate result of these actions. The author desires to express his thanks to Mr. I. Gilbertson for his assistance in carrying out the experiments.

DISCUSSION.

The CHAIRMAN said that he had been much impressed by Vieweg's results, and recognising in them important commercial possibilities, quite apart from their theoretical interest, had at once repeated some of his experiments. Bleached cotton yarn in skeins was treated with a 12 per cent. solution of caustic soda, and with the same strength of caustic soda containing 15 per cent. salt in solution. In the first place the shrinkage was not as great after the addition of salt as before, and on dyeing the two skeins together in a direct colour, that which had been treated with caustic soda and salt came out considerably lighter in shade. Quantitative dye trials were then undertaken in which untreated cotton, cotton treated with a 12 per cent. solution of caustic soda and cotton treated with this strength of caustic soda with 15 per cent. salt added, was dyed in Diamine Sky Blue, Chrysophenine and Benzopurpurine 4B. The amounts of colouring matter taken up were estimated in the dyed skeins by titration (indirect) with titanous chloride with the following results:—

	Untreated.	Treated with sodium hydroxide.	Treated with sodium hydroxide and salt.
	Per cent.	Per cent.	Per cent.
Diamine Sky Blue...	1.06	1.66	1.25
Chrysophenine	0.74	1.17	1.01
Benzopurpurine 4B..	1.02	1.97	1.67

He had also estimated the amounts of Benzopurpurine in the cotton used in Mr. Hübner's experiments and the results bore out those obtained in his own. His yarn, which had been treated with the 12 per cent. caustic soda solution with salt, contained 0.31 per cent. colouring matter, and without salt 0.36 per cent. With the 20 per cent. solution of caustic soda the difference was 0.39 per cent. with salt and 0.45 per cent. without. The joint results seemed fairly conclusive evidence that Vieweg's inferences could not be accepted as correct.

Mr. R. E. CROWTHER observed that when the notice of Vieweg's patent came out it appeared as though mercerisation on the commercial scale were going to be revolutionised. As they could not afford to miss anything that was likely to increase the profits of works he undertook experiments with a view to corroborating Vieweg's results. He assumed that the absorption of dye was proportionate to the amount of mercerisation. Speaking of dyeing with substantive colours, he noticed, as had been noticed by both the speakers that evening, that both Vieweg's inferences and Miller's remarks were incorrect: the addition of salt to a caustic soda lye produced a marked effect in mercerising, but that effect was in the opposite direction inferred in Vieweg's remarks. That opened up another question. Was it definitely settled whether the absorption of caustic soda was in proportion to the amount of mercerisation? From experiments he had performed

it appeared as though the amount of mercerisation was proportionate to the amount of caustic soda absorbed. Until that question was settled he did not think Vieweg's absorption figures could be altogether disputed. He had found the zinc chloride-iodine reaction more delicate than the dyeing with direct colours. In every case where he had used it the colour difference was much greater than that shown by dye trials, particularly if the caustic soda used for mercerising was only of a low strength. His experiments certainly seemed to bear out the results, as far as the absorption of dye was concerned, which had been brought forward during the evening.

Mr. W. F. A. ERMEN stated that he had tried the addition of salt to the soda lye and in every instance the lustre had suffered.

The CHAIRMAN thought the bulk of the evidence showed that Vieweg's inferences were untenable. Mr. Crowther and Mr. Ermen, from different points of view, had borne out what Mr. Hübner had put forward.

Mr. JULIUS HÜBNER, in reply to Mr. Crowther, said that it had not been the object of his note, nor, he believed, of Dr. Knecht's communication, to show whether Vieweg's statement with regard to the amount of caustic soda absorbed was correct. So far, however, all the evidence had clearly shown that the absorption of caustic soda and the degree of mercerisation were going parallel.

THE EXAMINATION OF CARBON TETRACHLORIDE.

BY L. G. RADCLIFFE.

Some time ago the author had his attention called to the fact that when carbon tetrachloride was mixed with phenylhydrazine and the whole allowed to stand an energetic reaction took place, with the evolution of heat and the formation of a solid compound. This was at first thought to be due to the presence of carbon bisulphide in the carbon tetrachloride, giving rise to the production of the well known compound $(C_6H_5NHNH_2)_2CS_2$. A subsequent examination of this white compound showed it to be free from sulphur and that, moreover, chemically pure carbon tetrachloride gave exactly the same result. This compound was a white crystalline substance melting between 198° and 200° C., and dissolved with difficulty in water but was freely soluble in alcohol or ether. Its alcoholic solution is turned red by alkalis, the colour being discharged again on the addition of acids.

During the course of these experiments it was observed that carbon tetrachloride generally did contain some carbon bisulphide and it was thought likely that it could be estimated by the reaction known to take place between carbon bisulphide and triethylphosphine. On adding triethylphosphine to commercial carbon tetrachloride dissolved in dry ether, a pink coloration resulted for a moment, and then a white precipitate formed and the colour vanished; on adding triethylphosphine to uniluted carbon tetrachloride, a violet reaction took place with the ignition of the triethylphosphine. Finally a solution of chemically pure carbon tetrachloride in absolute ether was mixed with a solution of triethylphosphine similarly diluted, and there resulted the instantaneous formation of a white precipitate, which on examination was found to contain carbon, hydrogen, chlorine, and phosphorus, but no sulphur. This white compound is therefore probably a molecular combination of carbon tetrachloride and triethylphosphine, but the examination was not continued, because it was evident that triethylphosphine was useless for the detection or estimation of carbon bisulphide in the presence of carbon tetrachloride. This triethylphosphine compound appears to decompose to an oily substance on standing, but this and also the phenylhydrazine compound are being investigated.

The foregoing experiments having shown that carbon tetrachloride behaved very similarly to carbon bisulphide, far as certain reactions were concerned, it was thought of interest to make a careful examination of the carbon tetrachloride of commerce, and to ascertain the percentage

of carbon bisulphide it contained, if possible by physical methods. The following series of determinations was made on Kahlbaum's pure carbon tetrachloride and pure carbon bisulphide and on two samples of commercial carbon tetrachloride. (The full figures are given for only one of these samples.)

TABLE I.

	Commercial carbon tetrachloride.	Pure carbon tetrachloride.	Pure carbon bisulphide.

Fractional distillation of 100 c.c.	B.pt.	$n_{D}^{18^\circ}$	B.pt.	$n_{D}^{18^\circ}$	B.pt.	$n_{D}^{18^\circ}$
One drop	67°	—	76°	—	45.6°	—
10 cc.	74°	1.4791	77.8°	1.46156	45.9°	1.6293
20 "	75°	1.4773	78°	1.4616	45.9°	1.6298
30 "	76.3°	1.4716	78°	1.4616	45.9°	1.6296
40 "	77.3°	1.4667	78°	1.4617	45.9°	1.6294
50 "	77.8°	1.4637	78°	1.46175	45.9°	1.6295
60 "	78°	1.4625	78°	1.4618	45.9°	1.6295
70 "	78°	1.4617	78°	1.4619	46°	1.6294
80 "	78°	1.4618	78°	1.4617	46.2°	1.6292
90 "	78°	1.4619	78°	1.4618	48°	1.62887
97 "	78°	1.4620	78°	1.4619	48°	1.62887

Comparisons were then made by examining artificially prepared mixtures of known amounts of pure carbon bisulphide and pure carbon tetrachloride. Later it was found that a slight modification of Gastine's method (Comptes rend., 98, 1588) for the estimation of carbon bisulphide by converting it into potassium xanthate and then titrating this with $N/10$ iodine solution was extremely accurate even in the presence of carbon tetrachloride.

The method is as follows:—A flask containing 25 c.c. of alcoholic potash and loosely corked is accurately weighed, and about 1 c.c. of the sample of carbon tetrachloride is introduced by means of a pipette, care being taken to keep the end of the pipette close to the level of the alcoholic potash; the cork is then replaced and the flask and contents again weighed, this giving the weight of the sample taken. After standing for five minutes the mixture is made slightly acid by the addition of dilute acetic acid, using phenolphthalein as indicator. Distilled water is now added and the mixture, after well cooling, is treated with an excess of solid sodium bicarbonate, which dissolves forming a milky liquid; this is now titrated with $N/10$ iodine solution and starch indicator as usual. The end reaction is very sharp. The chemical changes are represented thus:—

- (1). $KOH + C_2H_5OH + CS_2 = C_2H_5KOS_2 + H_2O$, expresses the formation of potassium xanthate;
- (2). $C_2H_5KOS_2 + CH_3COOH = C_2H_5KOS_2 + CH_3COOK$, expresses the formation of free xanthic acid.
- (3). $2C_2H_5OS_2 + I_2 = 2C_2H_5OS_2 + 2HI$.

Potassium xanthate is decomposed by hot water as follows:—

The following table shows test analyses of mixtures of pure carbon tetrachloride with known amounts of pure carbon bisulphide (by weight) by the modified xanthate method of Gastine:—

TABLE II.

Known percentage of carbon bisulphide.			Found by analysis.	
	Per cent.		Per cent.	
Pure carbon tetrachloride ..	Nil.		Nil.	
Pure carbon bisulphide ..	100		100	
Do.	3.89		3.81	
Do.	5.53		5.42	
Do.	8.96		8.94	
Do.	11.3		11.3	
Do.	16.0		15.88	

Several samples of commercial carbon tetrachloride were then examined by fractional distillation, and the

refractive index of each fraction at 18° C. determined, and also the percentage of carbon bisulphide in them. The percentage of carbon bisulphide varied from as low as 0.1 to 3.05 per cent. The following table was the result of examining the sample which contained 3.05 per cent. of carbon bisulphide:—

TABLE III.

Distillate in fractions of 10 c.c. each.	Temperature of distillation.	Refractive index at 18°.	Percentage of carbon bisulphide.
	° C.		
10 c.c.	74	1.4701	—
20 "	75	1.4773	—
30 "	76.3	1.4716	—
40 "	77.3	1.4667	4.0
50 "	77.8	1.4637	3.0
60 "	78	1.4625	1.9
70 "	78	1.4617	1.33
80 "	78	1.4618	0.75
90 "	78	1.4619	0.35

In the residue in the flask 0.10 per cent. of carbon bisulphide still remained. This sample was also tested in Abel's flash-point apparatus to see if this amount of carbon bisulphide, *viz.*, 3.05 per cent., could be detected, but with negative result.

In conclusion, I have to thank Prof. W. H. Perkin, F.R.S., for a sample of triethylphosphine, and Mr. J. F. Dunworth for his valuable assistance in carrying out the numerous determinations.

DISCUSSION.

The CHAIRMAN said the author had apparently come across two new reactions of carbon tetrachloride which might prove to be of considerable theoretical interest. It was interesting to note that the highest amounts of bisulphide stated in the paper did not render the tetrachloride inflammable and he asked whether the author had determined at what percentage of bisulphide such a mixture would become dangerous, as far as fire risks were concerned.

Mr. H. L. TERRY inquired whether any commercial significance could be attached to the examination.

Mr. W. H. COLEMAN asked whether the author had tried the method of estimation of carbon bisulphide by converting it into ammonium thiocyanate by digesting with ammonium sulphide.

Mr. R. E. CROWTHER asked if the presence of carbon bisulphide in the tetrachloride interfered with its use in the estimation of oils and fats by Wijs' method.

Mr. L. G. RADCLIFFE said, in reply to Dr. Knecht's question, he had not been able to settle that point sufficiently to be able to make a definite statement. Chemically pure carbon tetrachloride was very costly, and it was not wise to use it over again for a flash-point test. He had used one sample containing as high as 6 per cent. of carbon bisulphide, and this did not flash. Beyond the 6 per cent. he could not say. In reply to Mr. Terry, he thought that it would undoubtedly be of considerable interest to users of carbon tetrachloride. He had not tried the method mentioned by Mr. Coleman.

THE PARTIAL MERCERISATION OF COTTON CLOTH.

BY J. H. LESTER, M.Sc.

In a case recently submitted to me for examination, some cotton cloth was found to show under the microscope very marked differences in appearance in different parts of the same fibre. In many places the fibre was straight, full, and round, as is characteristic of mercerised cotton, whereas in other places it was spiral, flattened, and showing the wide central canal of normal raw cotton. It obviously became of interest to inquire as to the cause of this difference, and it was at once noticed that the well mercerised fibres were also much more deeply dyed than those which

were unmercerised; indeed, many of the unmercerised fibres were barely tinted with dye, though the cloth as a whole was of a deep purple colour. A simple further examination sufficed to show in what parts of the cloth or yarn the unmercerised and undyed parts of fibres existed. On dissecting the cloth and examining the yarns, it was seen that there were light patches in each of the hollows or bends produced by the surface contact of the warp and weft threads. It will follow from the above that the undisturbed dyed cloth showed a level and deep shade of dye, but that when the yarns were disturbed, either by tearing or otherwise, the minute light patches became visible. Examination under a very low power magnifying glass showed the effect most clearly. It was, of course, only to be expected that those parts of the cloth or fibre which were most completely mercerised should absorb the dye most completely, but I was greatly surprised to find such apparently enormous differences within such very short distances. In some instances the microscope showed three or four alternate lengths, well dyed and barely tinted, in the same ultimate fibre.

Upon such scanty information as the above, positive though I believe it to be as far as it goes, it would be unwise to found any comprehensive theory, but it appears quite warrantable to suggest that the mercerisation process may act first upon the surface fibres of cotton cloth; and where either the time, the temperature, or the strength of caustic solution are insufficient to effect complete mercerisation, the internal portions of the cloth where the fibres are brought into closest contact, will undergo mercerisation last.

DISCUSSION.

The CHAIRMAN observed that the conclusion to be derived from the author's observations was that there had been an uneven absorption of tannic acid.

Mr. JULIUS HÜBNER said the difference mentioned would not be anything like so pronounced if the pattern had been dyed with a direct dyeing cotton colour, but being mordanted with tannic acid the basic dye would show up more strongly.

Mr. R. E. CROWTHER inquired whether the warps were heavily sized or whether any precaution had been taken to remove the starch. It appeared to him there were physical differences in the state of the cloth previous to mordanting.

Mr. J. H. LESTER believed that there was a physical difference from place to place in the fibres themselves, and the varying intensity of the dye would follow upon that. As to what the treatment might have been was a matter of surmise. There must have been a fair amount of scouring to have given the cloth the level appearance it had, and also to account for the difference between the light and dark places being practically the same in the warp and the weft.

Newcastle Section.

Meeting held at Armstrong College on Thursday, 11th February, 1909.

MR. C. J. POTTER IN THE CHAIR.

THE BASES CONTAINED IN THE TAR FROM OTTO-HILGENSTOCK COKE-OVENS.

BY FREDERICK GEORGE TROBRIDGE, B.Sc.

It was thought that as the conditions of distillation in retort coke-ovens were very different from those in gas retorts, and very different qualities of coal were used in the two cases, the bases in coke-oven tar might exhibit differences from those in gas tar. Accordingly, 100 gallons of tar from Messrs. Priestman's plant of Otto Hilgenstock coke-ovens, Blaydon-on-Tyne, were washed with a 10 per cent. solution of sulphuric acid, the mixture being kept in a warm place to facilitate the separation of the acid from the tar. About 10 gallons of washings were

obtained of dark, brown-red colour, specific gravity 1.06, having a tarry smell, and still containing 6 per cent. of sulphuric acid. The liquid was first treated with steam in order to remove any volatile non-basic bodies. The residue was then made strongly alkaline by the addition of caustic soda and again treated with steam, 2000 grms. of basic oil being obtained. The bases which did not condense were passed over into dilute hydrochloric acid and were found to consist of ammonia with possibly traces of aliphatic amines.

The residue in the distilling vessel, from which the bases volatile in steam had been removed, contained a considerable amount of basic bodies non-volatile in steam, which separated as a thick tarry mass. On extraction with ether a part dissolved; the residue was a black, almost solid, basic substance, soluble in ethyl acetate; on long standing it set quite hard. The portion soluble in ether was a clear, dark yellow, almost solid base, easily and completely soluble in absolute alcohol, chloroform, benzene, and ethyl acetate, giving strongly fluorescent solutions. These bodies form hydrochlorides insoluble in ether but soluble in water to deep red solutions, which give microcrystalline precipitates with platonic chloride, mercuric chloride, stannous chloride, zinc chloride, and picric acid. On warming, however, the precipitates coagulate to oily masses.

The basic oil volatile in steam was distilled through a rod and disc still-head of 24 discs; the distillation was stopped when the temperature reached 170° C., 24 per cent. coming over below this temperature. Messrs. Brotherton and Co. of the Wear Fuel Works, Sunderland, inform me that about 70 per cent. of the bases from gas-tar distil below 140° C., whereas here we have only 24 per cent. below 170° C. The bases contained aniline, which was removed by means of the diazo-reaction, and the aniline-free base so obtained fractionally distilled 10 times.

The fractions boiling above 125° C. were each treated with mercuric chloride, a solution of the bases in hydrochloric acid being added to a hot solution (generally about 10 per cent.) of mercuric chloride. For the fractions up to 155° C. two molecules of mercuric chloride were used to one molecule of base; for those boiling above that temperature sufficient was taken to allow for three molecules of mercuric chloride to one of base, the calculations being made on the assumption that the fractions boiling between 125° and 150° C. were picolines and those between 150° and 165° C. lutidines. The bases boiling above 165° C. have not yet been examined. The mercury compounds were recrystallised from water slightly acidified with hydrochloric acid till further recrystallisation made no improvement in the melting point; the bases were then recovered by removing the mercury with hydrogen sulphide. The boiling points have been determined with standard short-scale thermometers, and melting points either with these or with one that has been checked against them. Attention is directed to the double compounds that the hydrochlorides of these bases form with platonic chloride. Great discrepancies appear in the values recorded by the various authors for their melting points; e.g., Brühl states that pyridine platinichloride melts at 240° to 242° C.; Calm and Buchka (Die Chemie des Pyridins) quote a series of values, namely 216°—218° C., 223.5° to 225.5° C., and 228°—229° C.; while Garrett and Smythe (Trans. Chem. Soc., 1902, Vol. 81) give 228°—229° C.

If pyridine platinichloride is prepared by adding a solution of platonic chloride to an acidified solution of the hydrochloride of the base in water and evaporating, crystals are obtained which melt at 241°—242° C., while a solution of the chloride is added to a solution of pyridine hydrochloride in absolute alcohol and crystals obtained by the spontaneous evaporation of the liquid without heating, the compound formed melts at 228° C. Also the compound prepared from aqueous solution differs from that from alcoholic solution in colour and crystalline habit, but not in chemical composition. An exactly similar state of affairs was found with the other bases examined, with the possible exception of γ -picoline, the bodies prepared from alcoholic solution always being lighter in colour and having lower melting points than those from aqueous solutions that have been heated. In

the cases which have so far been examined, the bodies obtained in the two ways do not differ in crystallographic system, and, in some cases, at any rate, these compounds could be converted the one into the other by recrystallisation from the different solvents. It seems that this furnishes an example of dimorphism in which the two substances belong to the same crystallographic system. The pyridine aurichloride certainly exhibits the same phenomena but those of the other bases only gave very slight indications of anything similar.

The following bases have been isolated:—

Pyridine	B.p. 115.2° C. at 759.4 mm.
2-Methylpyridine (α -picoline)	B.p. 128.8° C. at 749.7 mm.
4-Methylpyridine (γ -picoline)	Bp. 144.2° to 145° C. at 754.4 mm.
2,4-Dimethylpyridine (α , γ -lutidine) .	B.p. 158.2° C. at 753.4 mm.

Pyridine.—This base was obtained from the fraction boiling 110°—120° C. by removing the homologues of pyridine by heating with excess of a 5 per cent. solution of potassium permanganate. The platinum compound, prepared from an aqueous solution that had been heated, formed sparingly soluble red crystals of m.pt. 241°—242° C. without decomposition, and containing 34.33 per cent. of platinum. Obtained from absolute alcohol solution, the platinum compound gave sparingly soluble golden scales of m.pt. 228° C. without decomposition, and containing 34.38 per cent. of platinum (C_5H_5N)₂H₂PtCl₆ requires 34.33 per cent. of platinum.

The gold compound was prepared from alcoholic solution; it gave a mass of golden-yellow crystals sparingly soluble in cold, easily in hot alcohol, m.pt. 323° C. without decomposition, the fused mass however decomposing rapidly at 324° C. It contained 46.61 per cent. of gold. When prepared by the addition of gold chloride to an aqueous solution of pyridine hydrochloride, and heating for some time, fine lemon yellow crystals of distinctly lighter colour than those from alcoholic solution were obtained; these were sparingly soluble in cold, easily in hot water, and melted at 329° C. without decomposition. The fused substance decomposes at a slightly higher temperature. This compound contained 46.85 per cent. of gold ($C_5H_5N.HCl.AuCl_3$ requires 46.85 per cent.).

The picrate was prepared by addition of picric acid to an alcoholic solution of the base. It forms canary-yellow needles, easily soluble in water or alcohol, of m.pt. 163° C. without decomposition.

The density of the base was 0.9893 at 14° C. and the refractive index (sodium light) 1.5124 at the same temperature. The specific refraction, calculated on the Lorentz and Lorenz formula = 0.3038, and the molecular refraction 24.0.

2. *Methylpyridine (α -picoline)*. From the fraction boiling at 125°—135° C. a considerable quantity of a mercuric-chloride compound was obtained crystallising in small plates or stout prisms, of m.pt. 151° C.

It contained 59.69 per cent. of mercury

requires 59.61 per cent.). The base was a colourless liquid, easily soluble in water, and having a strong pyridine-like odour. The platinum compound, prepared from alcoholic solution, forms sparingly soluble yellow scales, of m.pt. 178° C. with decomposition, and contained 32.71 per cent. of platinum. (C_6H_7N)₂H₂PtCl₆ requires 32.72 per cent. From a heated aqueous solution the platinichloride was deposited as easily soluble orange-red prisms, of m.pt. 194° C. with decomposition. This product contained 32.53 per cent. of platinum. The gold compound was obtained from alcoholic solution as a mass of bright-yellow very easily soluble crystals, of m.pt. 175° C. without decomposition, and containing 45.32 per cent. of gold ($C_6H_7N.HCl.AuCl_3$ requires 45.33 per cent.). The aurichloride, prepared from a heated aqueous solution, appeared exactly the same in all respects. The picrate forms small, pale lemon-yellow needles, easily soluble in water or alcohol, of m.pt. 161° C. without decomposition.

The density of the base is 0.9530 at 14° C., the refractive index (sodium light), is 1.4966 at 14° C. The

specific refraction = 0.3070, and the
molecular refraction = 28.55.

The base was oxidised by a 5 per cent. solution of potassium permanganate, to picolinic acid, which crystallised in fine tufts, of m.pt. 134° C.

4. *Methylpyridine* (γ -picoline). From the fraction boiling at 145°–150° C. a mercuri-chloride compound was obtained in fine needles of m.pt. 121° C. which melt in hot water to a heavy oil. The base was a colourless liquid, soluble in water, with an odour similar to that of pyridine, but less pungent. The platinumchloride is very sparingly soluble in alcohol, crystallising in fine golden scales of the orthorhombic system. M.pt. 208° C. with decomposition. It contained 32.73 per cent. of platinum; $(C_6H_7N)_2H_2PtCl_6$ requires 32.72 per cent. When prepared from aqueous solution the platinum compound formed red crystals of the orthorhombic

soluble in alcohol and fairly easily in water. A quantity obtained from a heated aqueous solution appeared exactly the same in all respects. The compound contained 43.98 per cent. of gold ($C_7H_7N.HCl.AuCl_3$ requires 44.13 per cent.).

The picrate forms pale yellow crystals, easily soluble in water of alcohol, m.pt. 178° C. without decomposition.

The density of the base is 0.9378 at 14° C.; the index of refraction (sodium light)=1.5033 at 14° C.; the specific refraction=0.3151; and the molecular refraction=33.75. On oxidation with potassium permanganate, the base was converted into lutidinic acid, of m.pt. 235° C.

Below is a table comparing the values obtained for the melting points of the platinum and gold compounds of the above bases with those quoted by other workers.

Platinum Compounds.

Base.	Brühl.	Calm and Buchka.	Garrett and Smythe.	Author's Values.	
				From alcohol.	From water.
Pyridine ..	240°–242° C.	228°–229° C.	228°–229° C.	228° C.	241° C.—242° C.
α -Picoline ..	195° C.	178° C.	194° C.	178° C.	194° C.
γ -Picoline ..	231° C.	231° C.	—	208° C.	208° C.
α,γ -Lutidine ..	230° C.	219°–220° C.	216° C.	209° C.	216° C.

Gold Compounds.

Base.	Brühl.	Calm and Buchka.	Garrett and Smythe.	Author's Values.	
				From alcohol.	From water.
Pyridine ..	unchanged	at 285° C.	—	323° C.	329° C.
α -Picoline ..	167°–168° C.	167°–168° C.	—	175° C.	175° C.
γ -Picoline ..	205° C.	205° C.	—	203° C.	205° C.
α,γ -Lutidine ..	—	—	94°	77° C.	77° C.

system, of m.pt. 208° C. and containing 32.71 per cent. of platinum. The aurichloride, obtained from alcoholic solution, gave easily soluble bright-yellow needles, of m.pt. 203° C. without decomposition, and containing 45.22 per cent. of gold.

Prepared from a heated aqueous solution, the gold compound gave bright-yellow needles of m.pt. 205° C. without decomposition, and containing 45.46 per cent. of gold ($C_6H_7N.HCl.AuCl_3$ requires 45.33 per cent.). The picrate forms small crystals of pale lemon-yellow colour easily soluble in water or alcohol, of m.pt. 160° C. without decomposition. The density of the base is 0.9603 at 12.5° C. The index of refraction (sodium light) = 1.5065 at 12.5° C., the specific refraction is 0.3097, and the molecular refraction=28.80. This is practically the same as the value for α -picoline. On oxidation of the base with potassium permanganate, isonicotinic acid was obtained, m.pt. 312° C. in a sealed tube.

2.4. *Dimethylpyridine*, (α,γ -lutidine). From the fraction boiling at 155°–160° C. a mercury compound was obtained in the form of white, hair-like needles, of m.pt. 128.5° C., containing 58.49 per cent. of mercury. $C_7H_9N.HCl.2HgCl_2$ requires 58.35 per cent.

The base was a colourless liquid, more soluble in cold water than in hot, and having a rather pleasant odour. The platinumchloride was obtained from alcoholic solution as minute prisms with pyramidal ends, and of the monoclinic system; they melted at 202° C. with decomposition, and contained 31.13 per cent. of platinum ($C_7H_9N)_2H_2PtCl_6$ requires 31.25 per cent.

The platinum compound separated from aqueous solution as orange-red crystals of the monoclinic system, containing 31.15 per cent. of platinum m.pt. 216° C. with decomposition. The gold compound, prepared from alcoholic solution, formed a yellow oil, which crystallised on standing. The crystals melted at 77° C. without decomposition, and are easily

The author has pleasure in acknowledging his indebtedness to Messrs. Priestmans, Ltd., for their kindness in providing the raw material required, and to Prof. P. Phillips Bedson, in whose laboratory the work was carried out. The investigation is being continued.

Yorkshire Section.

Meeting held at Hull on Monday, January 18, 1909.

MR. F. W. BRANSON IN THE CHAIR.

A RAPID METHOD FOR DETERMINING CARBON DIOXIDE IN THE ATMOSPHERE.

BY S. H. DAVIES AND B. G. McLELLAN.

A rapid method of determining the condition of the atmosphere in schools, factories, and other places where people congregate, is of great importance. To do this with any certainty it is necessary within a brief interval of time to test the proportion of carbon dioxide at several points in the room. Given the number of people in the room and the area, it is then easy to calculate the rate of exchange of air for the room as a whole and to observe if the exchange is uniform, or whether there are any stagnant areas.

It is generally felt that Government regulations merely defining the cubic feet of space allotted to each worker in a factory, or each child in a school, must be replaced by regulations demanding a minimum exchange of air per head, supplied at a reasonable temperature.

In the First Report of the Departmental Committee appointed by the Home Office to inquire into the venti-

lation of factories and workshops (1902), the Commissioners concluded from their own observations that it is reasonable to expect under ordinary circumstances that 10 volumes of carbon dioxide per 10,000 should not be exceeded in factories or workshops unless gas is burning in the room. Their chief recommendation was that a standard of ventilation should be prescribed for all classes of factories and workshops not otherwise specially dealt with. This standard they defined as follows:—The proportion of carbon dioxide in the air at about the breathing level and away from the immediate influence of any special source of contamination (such as a person or light) shall not rise beyond twelve volumes of carbon dioxide per 10,000 of air, and that when gas or oil is used for lighting, the proportion shall not exceed twenty volumes after dark or before the first hour after daylight. Our experience, including many hundreds of tests on the air of workrooms, confirms that of the Commissioners, that it is possible to secure sufficient ventilation in workrooms to maintain this standard, and we regard any larger proportion of carbon dioxide than ten volumes per 10,000 to indicate unsatisfactory ventilation, and more than twelve volumes an excessive contamination. It is, however, useless for a Government Department to impose any such regulations unless the percentage of carbon dioxide can be determined rapidly and with sufficient accuracy. It is desirable that an accuracy of at least one unit of carbon dioxide per 10,000 shall be secured, and that the result shall be obtained within three to four minutes.

Pettenkofer's method, in which a large volume of air, varying from two to five litres, is collected and the carbon dioxide absorbed by baryta water, the excess of baryta being titrated back with oxalic acid, can be performed with great accuracy (as modified by Letts and Blake and others). Under industrial conditions, however, it is obviously impossible to collect a large number of samples by this method.

A gas volumetric method, in which the decrease in volume due to the absorption of carbon dioxide is directly measured, has been worked out by Haldane. His neat and portable form of apparatus is well known. Judging from our experience, however, of the difficulty in obtaining strictly consistent results with this apparatus, we fear that in the hands of men with the usual training of Medical Officers of Health or Sanitary Inspectors, it would give misleading results.

A third method, known as the minimetric method, was suggested by Dr. Angus Smith and has been developed by Lunge and Zeckendorf. In this the quantity of air is determined which is necessary to saturate the reagent used for the absorption of carbon dioxide. The apparatus used by Lunge and Zeckendorf consists simply of a bottle and a rubber bulb fitted with valves so as to allow the passage of air to take place only in one direction. A known volume of standardised baryta or sodium carbonate solution tinted with phenolphthalein is introduced into the bottle, and the volume of air required

to decolorise the solution is obtained by counting the number of compressions of the ball. This gives a measure of the proportion of carbon dioxide in the air. It is evident that this process is capable of considerable refinement, and by our modifications we have secured a rapid and sufficiently reliable process. Our apparatus is illustrated in the accompanying diagram.*

The pump for measuring the air is fitted with inlet and outlet valves, I and C, and delivers 50 c.c. of air at each full stroke. The inlet side is connected to a long glass tube supported by a clamp so that the air may be taken at a distance from the operator. The outlet is connected by a piece of rubber tubing to the absorption vessel, F.

Many experimenters have dwelt on the difficulty of titrating very weak solutions of baryta such as are required for this process, and on account of this difficulty we have abandoned the titration method, and, previous to making a series of tests, we standardise the solution against fresh air. The results of the most reliable investigators give proportions of carbon dioxide in fresh air varying from 3 to 3.5 parts per 10,000. The proportion seldom rises above 3.5, even in town air, except during foggy weather. As the variation is so slight, and as the majority of these tests will be made in a town atmosphere, we have adopted 3.5 parts per 10,000 as a standard.

Two solutions are required: the stronger stock solution is made as follows:—25 grms. of pure crystallised barium hydroxide (powdered) is placed in the bottle, A, and 1 litre of distilled water added. After corking, the contents are thoroughly shaken, until the baryta is dissolved. The cork is then replaced by a rubber stopper fitted with the tubes shown in the diagram. To one of these a measuring burette is attached, and the solution is protected by two soda-lime tubes. The weak solution which is used in the apparatus is prepared in bottle, B. Two litres of distilled water are placed in this bottle and a few c.c. of alcoholic phenolphthalein added. Strong baryta solution is added a few drops at a time and the bottle well shaken after each addition until the pink colour is just permanent. We have now precipitated the carbon dioxide present in the water. A further addition of 3.3 c.c. of baryta is now made and the solution, after shaking, is ready for standardisation. The bottle is fitted with a measuring pipette and protection tubes similar to those shown on bottle A. To standardise this solution the whole apparatus is placed on a table in front of an open window on the windward side of the room, the open end of the inlet tube projecting some feet out of the window. The apparatus is now completely washed out with fresh air by working the pump several times. A drop or two of phenolphthalein solution is placed in F, followed by a measured 25 c.c. of baryta solution run through tube J. A small hand blower, attached to K, is convenient for transferring the solution from the bottle to the pipette. The vessel, F, is now

* The apparatus is now being made by Messrs. J. J. Griffin and Sons, Ltd., Kingsway, London, W.C.

thoroughly shaken for 15 seconds and this is counted as one volume of air. 50 c.c. of air is then discharged, by means of the pump, into the vessel, F, which is again shaken for the same length of time. This is followed by another 50 c.c. and so on, until the solution is just decolorised; the number of strokes of the pump being counted. During the shaking it is an advantage to have a spring clip on the rubber tube, close to vessel F, to prevent the liquid from leaving the bottle. The solution should be of such a strength that 25 c.c. is exactly decolorised by 15 strokes (14 discharges from the pump and one for the air originally present in the bottle). If the solution is either too weak or too strong it is better not to attempt to modify it, but to start afresh, varying the quantity of strong baryta accordingly. Having standardised the solution against fresh air, the apparatus can be used to test the air of a room. The inlet tube should be placed at some distance from the operator, at least 3 ft. from any person in the room, and 3 ft. away from any wall. In an ordinary test of a workroom the sample should be taken at about the breathing level.

The accompanying table was constructed from a series of parallel determinations with Pettenkofer's method. It indicates the proportion of carbon dioxide per 10,000 corresponding to any given number of strokes.

Strokes of pump.	Parts carbon dioxide per 10,000.
15	3.6
14	4.0
13	4.5
12	5.0
11	5.6
10½	5.9
10	6.3
9½	6.7
9	7.2
8½	7.7
8	8.2
7½	8.7
7	9.3
6½	10.1
6	10.9
5½	11.7
5	12.7
4½	13.8
4	15.0
3½	16.4
3	18.0
2½	19.8

A note of the general condition and temperature of the atmosphere; of the air space available; the number of people present; the presence or absence of gas jets and of any open windows should accompany the result of this test.

The apparatus is handy to manipulate, and once the solution is standardised against fresh air, a youth can rapidly perform the tests *in situ*. The strength of the solution should be checked after each series of experiments. The apparatus involves the following modifications: (a) the accurate delivery of known volumes of air; (b) sampling at a distance from the operator; (c) standardisation of the solution against fresh air instead of titration; (d) special precautions for preventing access of carbon dioxide to the solutions.

DISCUSSION.

Mr. W. GATHORNE YOUNG thought that slight modification of the author's method, to secure accurate standardisation of the absorbent solution, and increase in capacity of the air pump, might be advantageous.

Mr. S. H. DAVIES said that the authors' method was sufficiently accurate for practical purposes. The highest proportion of carbon dioxide that he had seen recorded in a living room was 81 parts per 10,000 in a Glasgow lodging-house. It had been shown that 200 to 300 parts per 10,000 of pure carbon dioxide were necessary to give any marked physiological effect.

Mr. A. R. TANKARD thought that enlargement of the shaking cylinder, resulting in larger volumes of air and solution used, would probably be an improvement from the point of view of accuracy. Ammonia and obscure organic compounds often accompanied carbon dioxide, producing undesirable effects.

Dr. H. T. CALVERT pointed out that if a half-stroke of the pump was the limit of delicacy of manipulation this meant an error of 2 per 10,000 in the atmosphere they were then breathing. Another probable defect was that rapidity of movement of the piston might cause leakage.

Mr. B. G. McLELLAN said that for most ventilation problems where the carbon dioxide was between 7 and 10 parts per 10,000 the apparatus was quite sufficiently accurate. The volume of air and solution used had been arrived at after many experiments, and the apparatus as described combined portability with accuracy.

Journal and Patent Literature.

PATENT SPECIFICATIONS may be obtained by post by remitting as follows.—

English.—8d. each, to the Comptroller of the Patent Office, C. N. Dalton, Esq., Southampton Buildings, Chancery Lane, London, W.C.

United States.—1s. each, to the Secretary of the Society.

French.—1 fr. 25 c. each, to Belin et Cie., 56, Rue des Francs-Bourgeois, Paris (3e.).

German.—1 mark each (with full particulars), to Kaiserlich Patentamt, Berlin, Germany.

I.—PLANT, APPARATUS, AND MACHINERY.

PATENTS.

Drying machines; Continuous — for drying grain, peat, hops, salt, sand, cement, manures, chemicals, small coal, ores, and other analogous wet or moist materials. J. Black and A. H. H., and A. B. Lennox, Newcastle-on-Tyne. Eng. Pat. 1455, Jan. 21, 1908.

The dryer is formed of a number of superposed, vertical, flanged cylinders, bolted together and having a plate, forming a shelf bolted between each pair of flanges. A central shaft or centrally disposed cylinder attached to a shaft and rotated from below, has scrapers attached to it corresponding with each shelf. The material is introduced above the top shelf, and after completing the circle of the shelf, is discharged by the scrapers, through an opening, on to the shelf below. The drying medium enters above

the lowest shelf and circulates upwards, being forced to travel in the opposite direction to that taken by the material, by partitions or flaps depending from the shelf above and situated behind the openings.—W. H. C.

Drying, roasting, or otherwise treating pulverulent or granular materials. J. and C. McNeil, Govan, North Britain. Eng. Pat. 4491, Feb. 28, 1908.

The material to be treated is fed into one end of a horizontal, rectangular, metal vessel mounted on a hollow, perforated shaft and rotated by gearing. A number of inclined blades project inwards from each side of the vessel and form what is practically a screw or helix, which as the vessel is rotated, lifts up the material, drops it again and at the same time moves it forward through the vessel to the other end, from which it is discharged. Hot air or any other suitable drying or treating medium is introduced through the hollow, perforated shaft.—W. H. C.

Raising acids or other liquids by compressed air, steam, or other elastic fluid under pressure; Self-acting apparatus for —. W. Rayne, Manchester. Eng. Pat. 7054, March 31, 1908.

Two pressure-vessels, C, C', are filled alternately with the liquid to be raised, through the pipes, A, A', provided with non-return valves, B, B'. In these vessels, floats, E, E', are suspended by rods which pass through the pipes, H, H', from the air-escape valves, F, F', which are themselves suspended by adjustable clips from the arms of the pivoted beam, K. The ends of the beam are connected by links with the air-valves, G, G', which control the supply of compressed-air conveyed by the branches, J, J', from the air-main, I, provided with the stop-valve, L. Supposing the vessel, C', to be just filled and C, emptied, the float, E', rises and the beam overbalances into the position shown. The air-escape valve, F', closes, the air-supply valve opens and the liquid is forced out of C', through the rising main, D'. The vessel, C, is filling during this time. As soon as C' is empty and C, full, the beam, K, overbalances in the opposite direction and the contents of C are forced out through the pipe, D. The apparatus is started and stopped by opening or closing the stop-valve, L.—W. H. C.

Elevating liquids by means of gaseous fluids under pressure. V. Schwaninger, Oggersheim, Germany. Eng. Pat. 23,175, Oct. 30, 1908.

THE apparatus consists of a pressure chamber, 1, provided with a pipe, 2, of conducting material which is insulated from the vessel, 1. The liquid to be elevated enters by the pipe, 4, and the non-return valve, 3, the air escaping through the spring-controlled valve, 8, into the atmosphere. When the liquid has filled the vessel, it comes into contact with the conductor, 15, which is connected by the wire, 16, insulated at 34, to the electro-magnet, 17. The circuit is completed by the wire, 33, the battery, 18, and the wire, 19, connected to the conducting pipe, 2. The circuit being closed by the liquid, the magnet, 17, attracts the armature, 27, which raises the end of the lever, 11, and lifts the compressed fluid inlet valve, 7, which is normally closed by the weight of the lever. The compressed fluid enters the vessel, 1, through the pipe, 5, closes the air escape-valve, 8, against the spring, 14, and forces the liquid out of the vessel through the rising main, 2. In order to prevent the circuit being broken as soon as the

level of the liquid falls below the contact, 15, a conducting wire, 20, insulated at 32, dips into the liquid in the vessel, the depth to which it enters the vessel being adjusted by the sleeve contact, 40. This is connected by the rod, 21, to the sliding contact, 22, attached to the hinged arm, 25, which is connected by the rod, 28, to the armature, 27. When the circuit is closed, the arm, 25, is lifted by the armature and the contact, 23, is brought against the contact, 24, and remains in this position until the level of the liquid falls below that of the bottom of the wire, 20. When this happens the circuit is broken and the armature, 27, drops, closing the valve, 7, and separating 23 and 24. The vessel, 1, then commences to fill again.—W. H. C.

Concentration of solutions and recovery of volatile solvents.

D. Dubois. 1st and 2nd Additions, dated Sept. 2, 1908, to Fr. Pat. 384,907, Dec. 11, 1907 (this J., 1908, 494).

In order to prevent the blocking up of the taps, connecting pipes, and pumps between the various parts of the apparatus described in the original patent, owing to the deposition of the sulphur, or other dissolved material when the solutions are cooled during their passage through the connections, the latter are kept warm. This may be effected by surrounding them with steam jackets or by any other suitable means. In the case of the outlet taps, the latter are placed within the vessel and are thus kept at such a temperature that no deposit takes place.

—W. H. C.

Exhauster for acid gases. Selwig und Lange Maschinenfabrik. Fr. Pat. 393,941, July 2, 1908.

THE fan-wheel and blades are constructed of aluminium, preferably cast aluminium, and the casing is of earthenware. The aluminium fan-wheel is said to resist acid vapours for a considerable time and to be much less liable to disruption than fan-wheels of earthenware.—W. H. C.

Agitation and separation of mixtures of solids and liquids. J. T. Carriek and B. S. Pattison. Fr. Pat. 394,133, July 11, 1908.

The patent relates to a method of agitating solids with liquids, and subsequently separating the two, and its application to the treatment of copper matte with acid is described. The treatment is carried out in a closed vessel provided with a false bottom constructed of a suitable filtering material. The hydrogen sulphide produced by the action of the acid on the matte is withdrawn from the upper part of the vessel, and, by means of a fan, forced in again at the lower part through a number of tuyères disposed just above the filtering material. The mixture is thus kept agitated during the treatment. When the decomposition of the matte is complete, the fan is stopped, and the hydrogen sulphide is displaced by steam, and led away to be utilised. The outlet for the liquid, below the filtering layer, is then opened, and to prevent caking of the precipitate on the filtering material, the fan is put in communication with the atmosphere, and air is blown in through the tuyères. The treatment and the filtration may, if desired, be performed in separate vessels. The process is applicable to all operations of a similar character to that described.—A. S.

Filter-press; Continuous —. C. C. Leclaire. Fr. Pat. 394,450, Nov. 26, 1907.

The liquid to be filtered is forced under pressure into a vertical cylinder, the walls of which form the filtering surface, and which is surrounded by a closed vessel to receive the filtrate. A vertical shaft driven from above passes through the cylinder and is provided with scrapers which detach the deposited solids from the inner surface of the filter. The lower end of the cylinder terminates in a conical discharge chamber in which the solids are compressed and then discharged by a conical screw fixed to the lower end of the central shaft. In order to facilitate the detaching of the solids from the filter surface, periodical horizontal blows or shocks are communicated to the central shaft to cause it and the scrapers to vibrate. From the discharge opening the solids may, if desired, be passed through a tube where they are washed, dried, or otherwise treated.—W. H. C.

Distillation apparatus. A. Gohmann. Ger. Pat. 205,773, Oct. 6, 1907.

The apparatus consists of a column built up of a number of superposed compartments, through which the liquid to be distilled and the heating gases or vapour flow, in zig-zag paths, in opposite directions. In the bottom of each compartment are fixed, as usual, two pipes, one through which the liquid flows into, and the other through which the vapour rises from, the compartment below. Above the bottom of each compartment is mounted a corrugated hood, the corrugations of which dip into the liquid, thus causing the heating vapour and liquid to come into intimate contact with each other.—A. S.

Volatile and liquid products; Apparatus for the purification and vaporisation of — by means of a blast of steam. P. Wachtel. Ger. Pat. 205,911, June 20, 1907.

From the receptacle containing the liquid to be purified or volatilised, rises a tube ending in a jet. A jet of steam is blown across the end of this tube, at right angles thereto, and by an injector action carries the liquid with it into a system of piping, in which are arranged baffle-plates. The baffle-plates are provided with perforations, the size of which decrease from the first plate onwards, and thus the steam and liquid are intimately mixed, whilst solid impurities are retained by the baffle-plates. The pipe supplying the steam-jet is surrounded by two concentric pipes, which can be rotated independently and are provided with holes, so that by suitable adjustment, the steam pipe can be cooled by the outer air or by any desired cooling agent, and thus the temperature of the steam can be regulated. A similar cooling device may be applied to the system of piping into which the mixture of steam and liquid is blown.—A. S.

Non-aqueous mixtures; Method of preparing — and product thereof. E. G. Acheson, Stamford, Canada. U.S. Pat. 911,358, Feb. 2, 1909.

SEE Fr. Pat. 384,698 of 1907; this J., 1908, 494.—T. F. B.

Centrifugal [separating] machine. A. J. Ericsson, Assignor to Aktiebolaget Separator, Stockholm. U.S. Pat. 911,652, Feb. 9, 1909.

II.—FUEL, GAS, AND LIGHT.

Pulverised fuel for industrial furnaces. R. K. Mcade. Amer. Inst. Chem. Eng., Dec., 1908. Electrochem. and Met. Ind., 1909, 7, 61—62.

AFTER referring to the fact that in the United States powdered coal is practically the only fuel used in the manufacture of Portland cement, the author recommends its use for open-hearth metallurgical furnaces. The disadvantage of the ash settling upon the charge is not serious, since most of it is carried off by the strong draught. (For methods of burning powdered coal see this J., 1896, 888; 1900, 521; 1902, 1019; 1905, 369.)—A. S.

Coal; The coking property of —. O. Boudouard. Compt. rend., 1909, 148, 348—351.

COAL was treated with various organic solvents. All of these, excepting pyridine, extracted only very small quantities of brown tarry matter; pyridine extracted more than 10 per cent., and to a certain extent affected the coking power unfavourably. Strong hydrochloric acid had no action on coal; strong sulphuric and nitric acids destroyed the coking power, and oxalic acid was formed by the latter. Aqueous potassium hydroxide solution did not affect the coking power, nor did it remove humic acid. Both fusion with potassium hydroxide and the action of Schweitzer's reagent (ammoniacal copper solution) diminished the coking power appreciably, oxalic acid being formed in the former case. The successive action of aqueous potassium hydroxide solution, hot strong hydrochloric acid, and Schweitzer's reagent destroyed the coking power completely. The liquid obtained by treating coking coal with Schweitzer's reagent when treated with hydrochloric acid yielded a very small amount of a flocculent precipitate presenting all the characteristics of cellulose. The author concludes that the coking power of coals is caused by the presence of complex condensation-products of carbohydrates, and that the humic acid found in non-coking coals has been formed by the oxidation of these products. Anthracite is a product which has undergone so much oxidation that it no longer contains humic acid.—E. F.

Desulphurisation of spent oxide; Commercial o-dichlorobenzene as a solvent for the —. Chem. Fab. Griesheim-Elektron. J. Gasbeleucht., 1909, 52, 137—139.

COMMERCIAL o-dichlorobenzene, which consists of about 75 per cent. of o-dichlorobenzene and 25 per cent. of p-dichlorobenzene and has a flashing point of 62° C., dissolves 3.5 per cent. of its weight of sulphur at ordinary temperatures, 50 per cent. at 100° C., 200 per cent. at 110° C., 300 per cent. at 115° C., and mixes with sulphur in all proportions at 140° C. Laboratory experiments showed that spent oxide may be advantageously desulphurised by extraction with an equal weight of this solvent at 100° C. The crystallised sulphur obtained from the solution had a purity of 98.5 per cent. when the solvent had been used for six successive extractions of fresh quantities of spent oxide. The colour of the solution showed that tar became concentrated in the mother liquor; a small quantity of impurity was carried down mechanically with the crystals, but the purity of the sulphur was not increased by filtering the hot solution through wood-charcoal. The spent oxide was not dehydrated by extraction at 100° C., and the extracted product was as active as oxide desulphurised by extraction with carbon bisulphide at the ordinary temperature. The amounts of cyanogen, ammonia, and thiocyanic acid in the spent oxide were not decreased by the extraction.—A. T. L.

PATENTS.

Alcohol; Transforming — for the purpose of using it as a fuel. N. Manger, Paris, Eng. Pat. 23,806, Nov. 6, 1908.

A MIXTURE of ether and ethyl phosphide is produced by causing a stream of alcohol to flow continuously into a retort in which a mixture of alcohol and sulphuric acid and a 1 per cent. solution of white phosphorus in chloroform or some other suitable solvent, is heated. The product which distils over is a mixture of ethyl phosphide, ether, water, and alcohol; it is mixed with a small quantity of castor oil in which 1 per cent. of phosphorus has been dissolved, and is then suitable for use as a fuel for internal combustion engines.—W. H. C.

Coke-ovens and gas-producers; Portable — with portable base-pieces or hearths, applicable for use as furnaces or kilns. T. Smith, Newcastle-on-Tyne. Eng. Pat. 839, Jan. 28, 1908.

THE claim is for a metallic beehive- or dome-shaped, bottomless casing lined with firebrick, provided with an opening at the apex for charging, and lateral openings near the top for the escape of gases. In use it is fitted over a separate base on which the material to be treated rests. Both the casing and the base are provided with hooks by which they may be slung from a crane. Several ovens may be used together, being connected by movable pipes. If the coke produced is required for charging a furnace, the bottom-piece or base is hinged to the oven at one side. When the coking is completed, the cover and base are lifted together by chains or slings above the mouth of the furnace. The slings retaining the base against the cover are then released and the former swings on its hinge and allows the coke to fall into the furnace.—W. H. C.

Coke-oven; Horizontal regenerative — with horizontal flues. Act. Ges. f. Kohlendestillation. Fr. Pat. 394,077, Sept. 9, 1908.

EACH oven has a system of horizontal heating flues on each side as well as four flues beneath the sole of the oven. The side-flues are divided into two parts by a vertical partition, which is displaced horizontally from the centre line towards the coke-discharge side, so that each set of flues has the same total length, to ensure uniformity of heating. The flues on the ram side are connected in pairs with the regenerator on the coke-discharge side, and the flues on the discharge side with the regenerator on the ram side. The flues beneath the sole of the oven are also connected in pairs with the two regenerators.—W. H. C.

Water-gas; Process of making carburetted —. H. L. Doherty, New York, N.Y. U.S. Pat. 911,869, Feb. 9, 1909.

WATER-GAS is carburetted by mixing it with oil in the form of fine mist, and then passing the mixture through a heated mass of refractory material to fix the gas. The producer is blown with air in such a manner as to form mainly carbon dioxide, and the fixing chamber is heated by the sensible heat of the gases leaving the producer. The oil is sprayed by forcing it at a pressure exceeding 30 lb. per sq. in. through nozzles arranged so that the jets meet one another, particles of oil of sensible size being allowed to settle. The oil mist is then mixed with water-gas in regulated amounts and the mixture is passed through the fixing chamber.—A. T. L.

Water-gas generator. W. E. McKay, Milton, and H. N. Cheney, Boston, Mass. U.S. Pat. 911,899, Feb. 9, 1909.

THE generator is provided with movable grate-bars which can be operated from the outside without interrupting the working, and gas-tight sight-holes are arranged below the grate for viewing the base of the fuel bed. The generator may be worked continuously with alternating periods of blowing with air and with steam.—A. T. L.

Gas; Process of purifying —. E. L. Hall, Assignor to Security Savings and Trust Co., Portland, Oreg. U.S. Pat. 911,494, Feb. 2, 1909.

ILLUMINATING gas is first purified by the removal of sulphuretted hydrogen, then heated with or without the introduction of steam, to convert carbon bisulphide into sulphuretted hydrogen, and finally, the gas is again freed from sulphuretted hydrogen.—A. T. L.

Phosphoretted hydrogen [present in acetylene]; Fixation of —. Soc. Commerciale du Carbone de Calcium. Eng. Pat. 14,824, July 13, 1908. Under Int. Conv., March 6, 1908.

PHOSPHORETTED hydrogen is fixed and converted into phosphoric acid, and thus removed from gases such as crude acetylene, by means of a mixture of mercuric chloride, 10 parts; ferric chloride solution at 45° B., 600; ferric oxide (preferably obtained by precipitation, and dried at a low temperature), 250; to which 140 parts of dry infusorial earth or other inert substance may be added. The mixture forms a golden yellow, dry, and non-corrosive powder, which becomes white on use from the formation of ferrous oxychloride. The mercuric chloride acts only as a catalytic agent. The mixture also absorbs ammonia and hydrogen sulphide.—A. G. L.

Fuel, artificial; Manufacture of —. A. W. H. Vivian and G. L. Davies, London, and L. Grote, Tottenham. Eng. Pat. 2655, Feb. 6, 1908.

Solder or incandescent lamp filaments. H. Kuzel, Baden, Austria. U.S. Pat. 912,245, Feb. 9, 1909.

SEE Fr. Pat. 366,267 of 1906; this J., 1906, 1035.—T. F. B.

Candles. Fr. Pat. 394,362. See XII.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, PETROLEUM, AND MINERAL WAXES.

Carboniferous substances and bitumen. K. Charitschkow. J. Russ. Phys.-Chem. Ges., 1908, 40, 1327—1334. Chem. Zentr., 1909, 1, 576.

IN the destructive distillation of bituminous substances, products are obtained considerably different from those obtained in the distillation of coal. Asphaltum contains a larger percentage of hydrogen than coal does, and in accordance with this, yields "hydrogenised hydrocarbons" resembling the naphthenes obtained from petroleum. The author considers that there is a genetic relationship between the several natural carboniferous substances (coals, bitumens, petroleum), the differences being due to the different degrees of hydrogenation of such substances.—A. S.

Petroleum production of the United States in 1908. U.S. Geol. Survey, 1908. [T.R.]

THE great gain in production of petroleum in 1907 over 1906 required such a drain on all the great pools and developed so large a stock of unused crude oil that a further increase in 1908 was not to be expected, as a matter of either finance, trade requirements, or available petroleum resources. As the year went on, unprecedented floods in May and June and again in November brought disaster to the pipe lines of Oklahoma, and these storms also left a record of numerous oil tanks destroyed by lightning. In the Eastern fields the severe drought also seriously interfered with well drilling. The decline in production in the Glenn pool and in various Texas and Louisiana pools increased the likelihood of a total smaller than in 1907. Nevertheless, the actual record of the year shows a total beyond all records—between 175,000,000 and 180,000,000 barrels, compared to 166,000,000 in 1907. The total value is proportionately greater still, for the price of the product in California increased and it remained steady in other fields, except the Gulf, where a comparatively groundless fear of overproduction from the new Markham and Goose Creek fields caused depression. The increases

came from the steady growth in Illinois and California. Neither field showed phenomenal development. California responded to the higher prices consistent with depleted stocks, and Illinois showed the continued effect of the great investments of the previous year in this new territory.

PATENTS.

Hydrocarbons; Process for preparing — capable of absorbing water. J. Lifschütz. Ger. Pat. 205,428, July 23, 1907. Addition to Ger. Pat. 197,662, Feb. 8, 1907 (see this J., 1908, 554).

HYDROCARBONS are treated with oxidising agents, such as organic or inorganic peroxides.—T. F. B.

Petroleum and its distillates; Process for purifying crude —. L. Edelmann, Ploiesti, Roumania. U.S. Pat. 911,553, Feb. 2, 1909.

Lubricating oils. Fr. Pat. 391,992. See XII.

IV.—COLOURING MATTERS AND DYESTUFFS.

Indigoid dyestuffs derived from phenylisoxazolone. A. Wahl. Compt. rend., 1909, 148, 352—354.

ISATIN was transformed into its chloride by the action of phosphorus pentachloride in benzene, by Baeyer's method, and to the resulting solution a boiling benzene solution of an equivalent quantity of phenylisoxazolone was added. The colour of the solution changed to violet-red, and on heating on the water-bath a dyestuff was deposited in crystals with a coppery lustre. The yield was quantitative. The product, 3-phenylisoxazolone-2-indolindigo, has

the formula, $\text{C}_6\text{H}_5\text{C}=\text{C}=\text{C}(\text{NH})\text{N}(\text{O})\text{CO}\text{CO}\text{C}_6\text{H}_4$, and is insoluble in

water. It dissolves in aqueous alkali and is reprecipitated from the colourless solutions by acids, but if to these alkaline solutions sodium hydrosulphite is added, a yellow liquid is obtained from which acids no longer precipitate a coloured product; this is reproduced, however, if oxidising agents such as hydrogen peroxide are added. The leuco compound appears to have no affinity for animal or vegetable fibres. The three isomeric methoxyphenylisoxazolones were also prepared and converted into the corresponding methylated dyestuffs with isatin chloride.—E. F.

Aposafrairie; The azoxine analogue of —. F. Kehrman and W. Gresly. Ber., 1909, 42, 347—349.

By diazotising 3:6-diaminophenazoxonium chloride,

and boiling the resulting diazo compound with alcohol, one amino-group is removed and the chloride of the simplest azoxine dyestuff,

is formed. This dissolves in water or alcohol with a yellowish blood-red colour and dyes tannin-mordanted cotton in reddish-brown shades. The dyestuff is rather unstable, being decomposed on boiling its aqueous solution. When the corresponding nitrate is warmed in alcoholic solution with aniline, a greenish-blue dyestuff, probably corresponding with the formula,

is formed.—J. C. C.

PATENTS.

Indigo; Manufacture of chlorinated derivatives of —. Ges. für Chem. Ind., Basle, Switzerland. Eng. Pat. 19,793, Sept. 21, 1908. Addition to Eng. Pat. 9546, April 24, 1907 (this J., 1908, 116).

Tri- and tetra-chloro-derivatives of indigo are prepared by subjecting indigo to the action of chlorine, in the

presence of carriers of chlorine and in diluents consisting of benzene derivatives containing one or more negative groups or elements, as substituents. Such diluents are nitrobenzene, monochlorobenzene, dichlorobenzene, chloronitrobenzene, etc. The indigo is suspended in the diluent, antimony pentachloride is added, and chlorine is passed into the mixture, which is meanwhile stirred and cooled. When the increase in weight corresponds to the formation of the derivative desired, the mixture is left to stand; the chlorinated product is afterwards filtered off, and washed with hot alcohol, dilute hydrochloric acid, dilute caustic soda, and water, and is finally dried. These derivatives yield intensely blue shades on cotton, distinguished by their fastness to chlorine.—F. M.

Indigo; Production of halogen derivatives of —. Ges. f. Chem. Ind. in Basle. Sixth Addition, dated Nov. 11, 1907, to Fr. Pat. 375,514, Feb. 25, 1907.

SEE Eng. Pats. 6153 and 19,563 of 1908; this J., 1908, 893, 1200. Trihalogen derivatives of indigo can also be obtained by the action of chlorine on indigo or on mono- or dibromo-indigos suspended in an indifferent medium, such as nitrobenzene, and in presence of antimony pentachloride.—T. F. B.

Indigo-white; Stable — and process of making same. R. Wimmer, Assignor to Badische Anilin- und Soda-Fabrik, Ludwigshafen, Germany. U.S. Pat. 910,889, Jan. 26, 1909.

A MIXTURE of a solution of an alkali salt of Indigo-white and sulphite-cellulose waste liquor is evaporated in a vacuum. The product is readily soluble in water and is adapted for direct use in a vat.—J. C. C.

β -Hydroxythionaphthene and $\alpha\beta$ -diketodihydrothionaphthene derivatives and dyestuffs derived therefrom; Production of —. Badische Anilin und Soda Fabrik. First Addition, dated Sept. 3, 1908 (Under Int. Conv. Oct. 20, 1907), to Fr. Pat. 374,287, Feb. 4, 1907 (this J., 1907, 757).

$\alpha\beta$ -DIKETODIHYDROTHIONAPHTHENE or its derivatives may be prepared by condensing β -ketodihydrothionaphthene or its derivatives (not substituted by halogens in the thiophene nucleus) with aromatic nitrosoamines, according to the equation:

and hydrolysing the product. Example: 15 kilos. of β -ketodihydrothionaphthene are dissolved in 1500 litres of warm water by means of caustic soda, the solution cooled to 40° C., and a concentrated alcoholic solution of 15 kilos. of *p*-nitrosodimethylaniline added. Brown flocks separate which gradually pass into a violet-black crystalline powder. The dry substance, which has the constitution:

crystallises from benzene in greenish-red dichroic prisms, m.p. 176° C., containing half a molecule of benzene of crystallisation. On trituration with 15 per cent. hydrochloric acid, it furnishes $\alpha\beta$ -diketodihydrothionaphthene which separates out, whilst dimethyl-*p*-phenylenediamine remains in solution. Similar condensations of β -ketodihydrothionaphthene with *p*-nitrosodimethylaniline, *p*-nitroso-monoethylaniline and *p*-nitrosodiphenylamine and of 3-methyl- β -ketodihydrothionaphthene with *p*-nitrosodimethylaniline are described.—J. C. C.

Dyestuff and process of making same; Orange lake —. R. Lauch, Berlin, Assignor to Act.-Ges. f. Anilinfabr., Berlin. U.S. Pat. 912,138, Feb. 9, 1909.

A NEW orange dyestuff can be obtained by diazotising *o*-*p*-dinitroaniline and then combining with β -naphthol. The product can be used for preparing lakes.—P. F. C.

Vat [thioindigo] dyestuff; Production of a red —. Fabr. Bâloise de Prod. Chimiques. First Addition, dated Sept. 11, 1908 (under Int. Conv. Oct. 17, 1907), to Fr. Pat. 385,920, Jan. 3, 1908 (this J., 1908, 399, 681).

DYESTUFFS resembling those described in the chief patent are obtained by condensing acenaphthenequinone with

derivatives of 3-hydroxy-1-thionaphthene or of phenylthioglycolic-*o*-carboxylic acid containing a substituent in the benzene nucleus. Examples are given illustrating the use of 2-phenylthioglycolic-4-chloro-1-carboxylic acid, $C_6H_5(CO_2H)(S.CH_2.CO_2H)Cl(1:2:4)$, and of 4-ethylthio-oxythionaphthene in this condensation.—J. C. C.

Dyestuffs for wool: Process for the preparation of yellow —. Fabr. Prod. Chim. ci-dev. Sandoz. Second Addition, dated Sept. 4, 1908, to Fr. Pat. 387,245. Feb. 14, 1908 (this J., 1908, 801).

DYE STUFFS similar to those described in the first addition (this J., 1908, 1055) are obtained by replacing diazotised sulphanilic acid by diazotised β -naphthylaminemono-sulphonic acids, for example, 2-naphthylamine-1-sulphonic acid.—J. C. C.

Gallocyanine anilides; Production of new leuco-derivatives of —. Manuf. de Mat. Col. ancien. L. Durand. Huguenin, et Cie. Fr. Pat. 394,136, July 24, 1908. Under Int. Conv., July 31, 1907.

LEUCO-DERIVATIVES of arylaminogallocyanines or their sulphonic derivatives can be obtained by effecting the reduction of the dyestuffs in a medium which does not cause the elimination through heat of the arylamino-group. Suitable media are dilute alcohols, dilute ethyl tartrate, dilute formic acid, phenol, acetic, etc. The reducing agents may be hyposulphites (hydrosulphites) or their compounds, or sulphonylates, together with the corresponding quantity of hydrochloric acid, excess of the latter being avoided. The new dyestuffs give with metallic mordants, and particularly with chromium mordants, greenish-blue shades which are purer and faster than those produced by the corresponding sulphonic derivatives of the unreduced arylaminogallocyanines. Moreover they can be fixed on the cotton fibre by steaming for a short time.—J. C. C.

Azine dyestuffs; Production of —. Farbenfabr. vorm. F. Bayer und Co. Fr. Pat. 394,357, Sept. 16, 1908. Under Int. Conv., Nov. 5, 1907.

VIOLET to greenish-blue azine dyestuffs are obtained by oxidising a mixture of para-diamines or their derivatives containing at least one free amino-group and arylated 1:3-naphthylenediamines or their sulphonic acids by means of oxygen, air, or other gaseous mixtures containing oxygen, in the presence of ammoniacal copper oxide. In case the products are insoluble in water, they are rendered soluble by means of sulphonating agents. Example 1: 39 kilos. of diphenyl-1:3-naphthylenediaminesulphonic acid and 21.6 kilos. of *p*-aminodimethyl-aniline-*m*-sulphonic acid are dissolved together in 300 litres of alcohol with the addition of a solution of 50 kilos. of sodium carbonate in 300 litres of water: 5 litres of a concentrated ammoniacal solution of copper sulphate (containing 2 kilos. of copper sulphate) are added, and a strong current of air is blown through the solution, which is heated to 30°–50° C., until the diphenylnaphthylenediaminesulphonic acid has disappeared. Usually the dyestuff separates on cooling the solution, but if not, it is precipitated by adding salt. It dyes wool pure blue shades from an acid bath. Example 2: 51.4 kilos. of sodium diphenyl-1:3-naphthylenediamine-6:8-disulphonate are similarly oxidised together with 10.8 kilos. of *p*-phenylenediamine in 1600 litres of water. The resulting dyestuff gives violet shades on wool in an acid bath. Example 3: 31 kilos. of diphenyl-1:3-naphthylenediamine and 10.8 kilos. of *p*-phenylenediamine are dissolved in 300 kilos. of alcohol and oxidised as above. The product is sulphonated with fuming sulphuric acid. The resulting sulphonic acid dyes wool from an acid bath a violet shade.—J. C. C.

Anthraquinone series; Process for preparing thiocyanates of the —. Farbenfabr. vorm. F. Bayer und Co. Ger. Pat. 206,054, Dec. 12, 1907.

THE thiocyanates of anthraquinone or its derivatives are easily obtained by heating the diazothiocyanoates of anthraquinones with water, without the use of copper thiocyanate.—T. F. B.

Triphenylmethane dyestuffs; Process for preparing red, acid —. Farbwerke vorm. Meister, Lucius, und Brüning. Ger. Pat. 205,758, Nov. 29, 1906.

BENZALDEHYDEDISULPHONIC acids are condensed with mono- or dialkyl-*m*-aminophenols or their homologues, the pyrone ring is closed by heating with substances which remove water, and the leuco-disulphonic acid thus produced is oxidised to the triphenylmethane dyestuff. The products are readily soluble, and produce fast, red dyeings.—T. F. B.

Anthrapyrimidones; Process for preparing —. Farbwerke vorm. Meister, Lucius, und Brüning. Ger. Pat. 205,914, Nov. 5, 1907. Addition to Ger. Pat. 205,035, Nov. 5, 1907. (See this J., 1907, 85.)

ANTHRAPYRIMIDONES are obtained by heating α -halogen-anthraquinones with urea, preferably in presence of an indifferent solvent and a metallic salt (e.g., cupric chloride or sodium acetate).—T. F. B.

[Azo] dyestuffs suitable for wool: Manufacture of yellow —. G. B. Ellis, London. From Chem. Fabr. vorm. Sandoz, Basle, Switzerland. Eng. Pats. 3373, Feb. 14, 1908, and 12,787, June 15, 1908.

SEE Fr. Pat. 387,245 of 1908 and Addition thereto; this J., 1908, 801, 1055.—T. F. B.

Leuco-derivatives of anilides of gallocyanines or their sulpho-derivatives; Manufacture of —. L. Durand, Huguenin, et Cie., Haningen, Germany. Eng. Pat. 16,207, July 30, 1908. Under Int. Conv., July 31, 1907.

SEE Fr. Pat. 394,136 of 1908; preceding.—T. F. B.

Monoazo dyestuff: Red —. E. Ulrichs, Elberfeld, Assignor to Wülfing, Dahl, und Co., A.-G., Barmen, Germany. U.S. Pat. 911,186, Feb. 2, 1909.

SEE Fr. Pat. 381,204 of 1907; this J., 1908, 117.—T. F. B.

Indigos; Process of making dibrominated halogenated —. Farbwerke vorm. Meister, Lucius, und Brüning. Fr. Pat. 394,746, Dec. 5, 1907.

SEE Eng. Pat. 26,538 of 1907; this J., 1908, 975.—T. F. B.

V.—PREPARING, BLEACHING, DYEING, PRINTING, AND FINISHING TEXTILES YARNS, AND FIBRES.

Cotton from British Guiana. Bull. Imp. Inst., 1908, 6, 383–387.

SAMPLES of cotton cultivated in British Guiana were examined and the results compared with those obtained from samples of the same kinds of cotton examined in 1907. The results are given in a table and show that in general the cottons had retained their good qualities. Samples of six varieties of cotton cultivated by natives in the southern part of the Colony were also examined. It is stated that all of them would be readily saleable in this country.—A. S.

Fibres from Fiji. Bull. Imp. Inst., 1908, 6, 387–390.

THE fibres examined were Sisal, Mauritius, and bowstring hemps, and ramie ribbons and filasse. The results for the three hemps are shown in the following table:—

	Sisal hemp.	Mauritius hemp.	Bowstring hemp.
	Per cent.	Per cent.	Per cent.
Moisture	8.7	9.5	8.6
Ash	0.5	1.0	0.5
* α -Hydrolysis (loss) ..	8.5	14.0	9.1
* β -Hydrolysis (loss) ..	10.7	16.5	12.1
*Acid purification (loss)	0.9	5.1	1.3
Cellulose	79.0	78.0	75.0

* See this J., 1907, 757.

The three fibres were stated to be of superfine quality and would be readily saleable in large quantities, but the bowstring hemp was rather short (2.5 ft.). The

Sisal hemp was valued at £34—£35 per ton (Mexican Sisal, £25—£27), the Mauritius hemp at £31 ("good average" Mauritius, £22 10s.), and the bowstring hemp at about £27 per ton.

The ramie ribbons were of a pale-greyish straw colour, and much stiffer than a standard specimen; the strength was normal. The ribbons would be worth about £25 per ton, compared with £25—£30 for hand-scraped China grass. The sample of "filasse" was somewhat inferior to standard samples.—A. S.

Silk; Composition and chemical structure of various species of —. E. Abderhalden. Z. physiol. Chem., 1909, 58, 334—336.

THE work of E. Fischer and the author on the hydrolysis of the proteins, the isolation of the products, and the constitution of the polypeptides has enabled them to obtain a fairly complete knowledge of the constituent groups and the order of their arrangement in the case of the fibroin of Italian silk (this J., 1906, 278). It is now proposed to examine a large number of commercial varieties of silks of other origin on the same lines, and to study the differences in composition and constitution. Such an investigation involves two directions of research: total hydrolysis and partial hydrolysis. By the total hydrolysis the constituent groups are isolated separately as simple amino-acids and their relative quantities determined. But two proteins may yield on total hydrolysis exactly the same amino-acids in identical proportions and yet be different as regards the order of arrangement of these groups in the original molecule. Such a difference is detected by partial hydrolysis, whereby aggregates of two or more of the ultimate groups are obtained in the form of di- or polypeptides, which can then be characterised by means of the data accumulated in earlier work. If all the products both of total and partial hydrolysis be identical, it is highly probable that the two proteins are identical both in composition and structure.—J. F. B.

Silk; Composition and chemical structure of various species of —. 1. The monoamino-acids of New Chwang silk. E. Abderhalden and A. Rikiet. Z. physiol. Chem., 1909, 58, 337—340.

NEW Chwang silk is a definite commercial variety, but the authors have no information as to the species of silkworm producing it, nor its form of nutrition; presumably the worm feeds on oak-leaves. The raw silk was cleaned mechanically and then degummed by repeated extraction with boiling water in an autoclave. The exhaustion was never absolutely complete, so it is assumed that even pure water under pressure has a slight hydrolysing influence on silk fibroin. The raw silk lost, in the course of four extractions of 3—5 hours each, 18.95—20.0 per cent. of its weight. The hygroscopic moisture of the raw silk was 10 per cent. (dried at 120° C.), the ash was 5 per cent.; the degummed silk retained 2 per cent. of ash. The fibroin was less susceptible to acid hydrolysis than that of Milan silk, and larger quantities were left unresolved, in the form of a black-coloured residue. The process consisted in a preliminary hydrolysis with 25 per cent. sulphuric acid, for the estimation of the tyrosine, followed by two consecutive treatments for six hours with boiling, fuming hydrochloric acid. The amino-acids were isolated and estimated by known methods, the results being calculated on the weight of the ash-free fibroin, corrected for the residue remaining unresolved after each hydrolysis. The following products were isolated: glycocoll, 19.7 per cent.; alanine, 23.8; leucine, 1.6; serine, 1.0; aspartic acid, 2.9; glutamic acid, 1.7; phenylalanine, 1.2; tyrosine, 9.8; and proline, 1.85 per cent.—J. F. B.

Fibres; Use of reactions between — and gases in the textile industry. F. Erban. Chem.-Zeit., 1909, 33, 169—171, 182—184, 191—192.

AN outline is given of the different methods that have been tried with gases as reagents in the separation and bleaching of fibres, and the dyeing, mercerisation, and printing of textile materials. From a consideration of the results the author concludes that, apart from the well-known methods of sulphuring wool and silk and the

fixation of metallic mordants and Aniline Black upon cotton by means of ammonia vapour, few of the attempts have met with success. The method of von Niederrhansen, however, in which sodium aluminate is fixed upon the fibre by means of carbon dioxide is now of considerable importance in the textile industry. None of the attempts to use chlorine in bleaching, or gases or steam in dyeing textiles with Aniline Black has, as yet, been followed up to any extent. Green's process (this J., 1908, 683, 854), should it prove practicable on a large scale, must be regarded as an advance of the greatest importance in the production of Aniline Black upon fibres.—C. A. M.

Lead stains in bleached cotton yarn. W. H. Pennington. J. Soc. Dyers and Col., 1909, 25, 46—47.

IN some cotton yarn which had been bleached with calcium hypochlorite and sulphuric acid, dark brown stains appeared which were found to be due to the presence of lead peroxide. The lead contamination was traced to the use of three wooden bleaching cisterns, formed of 4-inch planks jointed with red lead; the wear and tear on the cisterns had loosened the joints and exposed the red lead, which had been converted into peroxide by the bleaching liquor. In the discussion, other instances were mentioned of lead stains having been produced during bleaching; one, where lead peroxide had been produced by bleaching liquor flowing through a leaden pipe, another where the contamination had come from a leaden floor in the bleach house, and two cases where the stains were due to lead sulphide produced in the boiling kier: in one case the headings were from yarn dyed with Chrome Orange, and in the other the stains were caused by a leaden plate placed on the top of the kier.—F. M.

Waste dye liquors; Treatment of —. W. M. Mackey. J. Soc. Dyers and Col., 1909, 25, 38—45.

IN the method of treatment described, there is no new departure from the chemical point of view, the question being mainly one of precipitation of the organic matter and the removal of the matter in suspension. Lime, and "aluminio-ferrie" were the precipitants experimented with, and preliminary laboratory trials led to the conclusion that, for effluents from woollen dyeworks, lime was in general the most suitable precipitant, judged by the amount of total solids left in the treated water, the amount of absorbed oxygen, and the degree of alkalinity. In the case of an effluent from a cotton dyeworks, the use of "aluminio-ferrie" followed by lime gave the best result. The plant described consists of a large tank into which the effluent is pumped and there mixed with milk of lime. The outflow pipe leads to a small tank, which serves as a pressure break, and from this the effluent flows to the bottom of a cylindrical vessel (a disused boiler of about 8000 gallons capacity) inclined at an angle of 15°—25°. The rate of flow is about 3000 gallons per hour, and it is found that the sludge which accumulates at the lower end of the cylinder and through which the inflowing liquid has to make its way, assists in agglomerating the suspended matter and acts to some extent as a filter. The arrangement is efficient with a rate of flow below 5000 gallons per hour. The sludge is drawn off periodically, but sufficient is left in the cylinder to ensure the removal of the suspended matter from the inflowing treated effluent.—F. M.

PATENTS.

Artificial silk threads; Machines for producing —. G. Guadagni, Pavia, Italy. Eng. Pat. 12,253, Jan. 18, 1908. Under Int. Conv., Sept. 28, 1907.

THE filtered cellulose solution flows from a reservoir into a horizontal pipe, supplied on its upper side with short vertical branch pipes at intervals of 15—20 cm. Each of these short pipes is provided with a cock, and terminates in a glass nozzle. Around this glass nozzle is fixed a cylinder, fitted with inlet and outlet pipes, through which the coagulating solution flows. Upon leaving the nozzle, the thread rises in this cylinder and is led over a stretching roller, which is run at such speed

as is suitable to the rate of flow of the cellulose solution and the fineness of the thread desired. The driving roller is of the same diameter as the stretching roller and runs at the same speed; it is partially immersed in the washing tank and drives the reeling bobbin (which is entirely immersed in the washing liquor), by direct frictional contact.—F. M.

Artificial silk threads; Manufacture of —. A. Lecœur. First Addition, dated Nov. 14, 1907, to Fr. Pat. 392,869, Oct. 8, 1907 (this J., 1909, 88).

THE necessity of a thorough treatment of the thread in the second bath mentioned in the original patent is emphasised. The bobbin upon which the thread is wound remains in the bath for at least half an hour, and is then transferred to another vessel containing a dilute solution of sodium bisulphate.—F. M.

Artificial threads; Apparatus for the manufacture of brilliant —. T. Chandelon. Fr. Pat. 394,009, Sept. 7, 1908.

THE spinning solution is forced from a reservoir through a number of fine spinning nozzles into a trough, through which flows a steady stream of the coagulating reagent. The newly formed filaments are carried along by this stream and delivered on to the surface of a rotating drum, which is so arranged that the coagulating reagent falls on to it after flowing through the trough. In addition to carrying forward the continuous filaments, the drum is caused in this way to gather up any broken threads. The apparatus is provided with devices for regulating or stopping the flow through each spinning nozzle.—P. F. C.

Cellulose threads, filaments, ribbons or films; Manufacture of —. Soc. franc. de la Viscose. Fr. Pat. 394,586, Sept. 23, 1908.

THE invention relates to an improved coagulating bath for the continuous coagulation of solutions of viscose. In this bath a mineral acid is employed in conjunction with a substance which possesses the power of coagulating viscose without decomposing it. Suitable substances are: Glucose or a body of similar nature; glycerol or other organic compound, particularly an alcohol; acetic acid or other acid of the fatty series; lastly salts or a mixture of salts, particularly ammonium sulphate and magnesium sulphate. The proportions of the coagulating agents may be varied to suit particular conditions.—J. F. B.

Washing and bleaching compound; Production of a fluid —. F. Gallati-Grob, Luchsingen, Switzerland. Eng. Pat. 23,725, Nov. 5, 1908.

CLAIM is made for a solution containing, say, 1000 grms. of sodium peroxide and 1000 grms. of powdered borax in 6 litres of water, the liquid being subsequently filtered and drawn off into bottles.—C. A. M.

Bleaching and scouring of vegetable and animal fibres and fabrics, and paper pulp; Electrolytic apparatus having transporting aprons, applicable to the — and to treatment with all liquids. A. Dassonville. First Addition, dated Sept. 3, 1908, to Fr. Pat. 387,104, Feb. 10, 1908 (this J., 1908, 817).

THIS apparatus consists of a vat, having a perforated false bottom, and provided at its ends with sheets of carbon or metal which are used as electrodes. Between these electrodes several endless aprons are arranged, cross which strips of carbon and wood are alternately inserted. Each apron is mounted on two rotating vertical rollers which are erected at opposite ends of the vat. One of each pair of rollers has a fluted surface to prevent the aprons from slipping. The material under treatment is led by a transporting device underneath a jet of hot water and then into the vat containing the liquor necessary for the treatment. It is then dragged along the vat by the moving aprons and delivered at the other end on to a carrier which passes underneath a second jet of hot water and delivers the material into a suitable receiver.—P. F. C.

Washing and scouring of animal and vegetable substances. C. Villedieu. Fr. Pat. 394,921, Dec. 11, 1907.

1000 litres of a solution of sodium carbonate or sodium hydroxide of 2°B., 500 grms. of an organic substance

such as phenol or petrol dissolved in 2–3 litres of sodium or ammonium sulphocinoleate are added. The material to be treated is immersed in this mixture for about half an hour and then washed, first with dilute acid and afterwards with water.—P. F. C.

Mercerised tissues; Device for removing the alkali from — with suction devices for the diluted lye. C. G. Haubold, jun., Ges.m.b.H. Ger. Pat. 205,962, April 27, 1907.

IN order to recover the alkali from mercerised tissues in as concentrated a condition as possible, only just sufficient water to destroy the mercerising action of the lye is used. With the ordinary devices, in which the water is under more or less pressure, it is difficult to obtain uniform distribution of such a small quantity of water over the width of the tissue. According to the present patent, the tissue after leaving the mercerising tank passes below a receptacle arranged transversely, from which water overflows on to the material below. Underneath the material, immediately below the overflow devices, are suction nozzles through which the diluted lye is drawn away.—A. S.

Thioindigo Red; Process for discharging dyeings of —. Kalle und Co. Akt.-Ges. Fr. Pat. 394,568, Sept. 22, 1908.

THE dyed material is printed with a paste which contains 12 per cent. of Hydrosulphite N.F. conc. It is then dried, steamed at 108° C. out of contact with air, and immediately passed into a bath containing 250 c.c. of alcohol and 10 c.c. of hydrochloric acid per litre. By working the material in this bath for a few minutes at 40–55° C., the leuco-derivative remaining on it is removed without having the opportunity of re-oxidising, and pure whites are obtained. The process is applicable to other thioindigo dyestuffs.—P. F. C.

Lustreing and finishing silk threads; Process and machine for —. E. Pohl, New York. U.S. Pats. 911,906 and 911,907, Feb. 9, 1909.

THE threads are loaded by the application of a finishing or lustreing solution and are then dried and ironed. The individual fibres on the surfaces of the threads are laid flat by this treatment. The threads are next led through a vibrating guide and over the edge of a heated contact device. The longitudinal motion of the transversely vibrating threads over this device fractures the surface of the finishing material and releases the imprisoned surface fibres, allowing them to project laterally.—P. F. C.

Artificial horsehair and other cellulose products having resistance and elasticity; Manufacture of —. E. Crumière, Paris. U.S. Pat. 911,868, Feb. 9, 1909.

SEE Addition of March 17, 1908, to Fr. Pat. 377,118 of 1907; this J., 1908, 977.—T. F. B.

Wool; Impts. in, and apparatus for cleansing —. F. and C. Shuman, Tacony, Pa., U.S.A. Eng. Pat. 10,951, May 20, 1908.

Treating sugar-cane, etc. U.S. Pat. 909,987. See XIX.

VII.—ACIDS, ALKALIS, SALTS, AND NON-METALLIC ELEMENTS.

Sulphuric acid manufacture; Determining loss of sulphur trioxide in the wash gases of the contact process of —. H. Ljungh. Chem.-Zeit., 1909, 33, 143–144.

A SLOW stream of the exit-gases was aspirated through 600 c.c. of N/2 sodium hydroxide solution, and measured.

After passage of 1000—1500 litres, the excess of sodium hydroxide was determined in an aliquot portion of the liquid by means of hydrochloric acid and methyl orange, then the sulphite in the neutralised liquid was determined by making it up to a known volume, and running it from a burette into a known volume of $N/100$ iodine solution with starch indicator. The amount of acid required to convert this normal sulphite into acid sulphite, subtracted from the total found in the first titration, gave the amount equivalent to the sulphur trioxide in the volume of gas used (V litres), and hence the weight of sulphur trioxide (s grms.). If in 24 hours a kilos of sulphur are burnt, $2a$ kilos. of sulphur dioxide are produced; and if k per cent. of this are condensed, chiefly as trioxide, in coolers, filters, etc. (k being determinable only by actual measurement in each installation), there will reach the contact apparatus $\frac{a}{60} (100 - k)$ kilos., having at 0°C . and 760 mm.,

a volume of $0.00696a (100 - k)$ cb. m. If sulphur dioxide form p per cent. of the total volume of gases, this total volume will be $\frac{0.696a}{p} (100 - k)$ cb. m. If u per cent. of the sulphur dioxide be converted into trioxide (with half its volume of oxygen), and if $100 - f$ per cent. of the sulphur trioxide be absorbed, then the total volume of gases which escapes is

$$\frac{0.696a(100-k)}{p} - \frac{100-f}{100} \cdot \frac{1.5u}{100} (0.00696a)(100-k) \text{ cb. m.}$$

If these gases contain x grms. of sulphur trioxide, then the results of the experimental determinations above give that

$$\frac{0.696a(100-k)}{p} - \frac{(100-f)}{100} \cdot \frac{1.5u}{100} (0.00696a)(100-k) = \frac{V}{s}$$

But also, since x is the weight of f per cent. of the volume of sulphur trioxide entering the apparatus,

$$x = \frac{f}{100} \cdot \frac{1.5u}{100} (0.00696a)(100-k) (2.78) (1.2932) \text{ kilos.},$$

1.2932 kilos. being the weight of 1 cb. m. of air, and 2.78 the sp. gr. of gaseous sulphur trioxide. From these two equations the unknown quantity f can be eliminated, and it results that

$$x = \frac{2.5a(100-k) \left(\frac{1}{p} - 0.00015u \right) s}{3.6 V - s} \text{ kilos.};$$

and, s being negligibly small in comparison with V , the denominator may be written as $3.6 V$. If, instead of the absolute weight of sulphur trioxide escaping, it is preferred to express it as the percentage (F) of the total amount obtainable from the combustion of a kilos. of sulphur, then

$$F = \frac{100x}{32a} = 40 \frac{x}{a} = \frac{(100-k) \left(\frac{1}{p} - 0.015u \right) s}{3.6 V} \text{ per cent.}$$

The author has slightly modified the well-known Reich's apparatus for the iodometric determination of sulphur dioxide in the escaping gases (Lunge's "Sulphuric Acid and Alkali," 2nd edition, vol. i., 325—326). The exit-tube from the upper bottle is short, and is connected with the exit-stopcock by a piece of rubber tubing longer than the height of the bottle. The stopcock is clamped to the horizontal arm of a vertical rod, which passes through a clamp on the stand, and has at its upper end a horizontal pointer. This pointer, at the beginning and end of each observation, is made to coincide with the level of the water in the bottle, and thus the gas is measured always at the same difference from the barometric pressure.

—J. T. D.

Sodium alum. W. R. Smith. J. Amer. Chem. Soc., 1909, 31, 245—247.

SODIUM alum is obtained by allowing a solution containing aluminium and sodium sulphates to crystallise at a temperature below 30°C .; it forms mixed and layer crystals with other alums. With ordinary potassium alum, such crystals are not easily obtained, probably on account of

difference of solubilities. But sodium alum readily forms layer crystals with chrome alum. At 15°C . 100 grms. of water dissolve 111.3 grms. of crystallised sodium alum.

—F. SODX.

Chromic oxide; Solubility of —. M. Z. Jovitschitsch. Monatsh. Chem., 1909, 30, 47—50.

CHROMIC oxide, obtained from chromitite (see page 246), dissolves in nitric acid, contrary to the general statement that strongly ignited chromic oxide is insoluble in acids. To obtain pure chromic oxide, chromitite is ignited with lime and alkali carbonates, the fused mass extracted with hot water, and the clear aqueous solution saturated with hydrogen sulphide. The green precipitate is collected, carefully washed, dried at 100°C . and ignited at first over a Bunsen flame and subsequently for 10—15 minutes with a blast-flame. The dark green oxide is powdered, moistened with a few drops of water and warmed in a beaker with a little fuming nitric acid; subsequently ordinary nitric acid is added. After some 15 minutes, the acid is coloured green; when most of it has evaporated, the green liquid is poured off, fresh acid added, and the process repeated. In this way all but about 10 per cent. of the chromic oxide is brought into solution. The acid solution is evaporated on the water-bath till the nitric acid has mostly disappeared; the residue is dissolved in alcohol and again evaporated and this process is repeated. Finally the normal nitrate, $\text{Cr}_2(\text{NO}_3)_3$, is obtained in the form of a green crystalline mass with a reflecting surface as if varnished. This contains traces of acetate and oxalate, formed no doubt by the action of nitric acid on the alcohol. The nitrate absorbs three mols. of water in the air, but is not deliquescent. —E. F. A.

Gold and bromine; Combinations of —. F. Meyer. Compt. rend., 1909, 148, 346—348.

THE final product of the action of dry bromine on gold is the tribromide, AuBr_3 , which is readily obtained if the constituents are repeatedly heated, with shaking. It is a black compound, soluble in bromine and volatile in an atmosphere of bromine at about 300°C . No evidence of the existence of a dibromide, AuBr_2 , was obtained. At temperatures at which the tribromide dissociates, only one other bromide, the monobromide, AuBr , could be obtained. The dissociation-curves of the two bromides were studied, and the results are tabulated. —E. F.

Borates. Levi and Castellani. See XI.1.

PATENTS.

Hydrochloric acid; Manufacture of — by means of magnesium chloride. J. J. T. Schloesing. Fr. Pat. 394,037, Sept. 8, 1908.

THE process described in a former patent (this J., 1906, 477) is modified as follows:—To the solution of magnesium chloride, heated to 132° — 133°C ., powdered magnesia is added to the extent of one-third that required to form the ordinary oxychloride ($\text{MgCl}_2 \cdot \text{MgO} \cdot 0.6\text{H}_2\text{O}$). Heating and stirring are continued, until the mixture becomes pasty, when it is turned out and moulded into briquettes. These are dried at a low temperature (200°C .), and are then decomposed at a dull red heat, the decomposition into magnesium oxide and hydrochloric acid being effected by spreading the material on interspaced bars of refractory material in a heating chamber and passing the hot gases from an adjacent furnace or producer through the mass, from above downwards, in order to avoid crushing the friable product, steam being introduced into the chamber as required. The oxychloride formed in this process, which is claimed as new, decomposes like the ordinary oxychloride, and has the advantage of containing less magnesia, being more easily prepared, and readily moulded into briquettes. —F. SODX.

Bicalcic phosphate, magnesia, and potassium chloride; Process of simultaneously obtaining —. J. J. T. Schloesing. Fr. Pat. 394,207, Sept. 11, 1908.

SEA water or the mother liquor of salt marshes, after treatment with calcium chloride to precipitate the sulphate present, is allowed to evaporate spontaneously to a

strength of 32° B., when nearly all the sodium chloride is deposited. It is then further concentrated, by heating, to 34.5° B., by which time the potassium chloride is, in great part, deposited as the double chloride of potassium and magnesium. This double salt is decomposed by a known method, the magnesium chloride returning into solution: the solution contains also a little potassium chloride, and to prevent this interfering with the decomposition of the magnesium oxychloride later, a quantity of sulphate equivalent to it is allowed at a previous stage to remain in the liquid. The solution of magnesium chloride is then concentrated, until it boils at 133° C., and dealt with as described in the preceding abstract to give magnesia and hydrochloric acid which is condensed in a coke tower. The acid is used to dissolve tricalcic phosphate, and from the solution bicalcic phosphate is precipitated by the addition of lime, the calcium chloride solution formed being utilised in the first part of the process.—F. SODN.

Quicklime; Process and apparatus for slaking — W. Schulthess. First Addition, dated Sept. 7, 1908, to Fr. Pat. 390,357, May 18, 1908 (this J., 1908, 1018).

AN apparatus is described suitable for slaking quicklime which has been crushed to a mixture of fine powder and small lumps. The process of charging and discharging the slaking chamber is made continuous by means of mechanical measuring devices which regularly deliver the material on to feeding and discharging worms. The material to be treated, should be heated to about the temperature of the steam used in slaking, before it enters the slaking chamber, in order to prevent condensation of water upon it, and the slaking chamber itself and the receptacles connected to it are jacketed for the same purpose. It is sometimes preferable to slightly moisten the lime immediately before slaking, and this is effected by treating it with a spray of water from a pipe fixed above the feeding worm.—F. SODN.

Soft limestones; Process for burning — F. M. Meyer. Fr. Pat. 394,354, Sept. 16, 1908.

SOFT chalks, calcareous marls, etc., cannot be burned in the ordinary way and become overburnt in a rotary kiln. They are, however, satisfactorily burned in the latter, if the material and fuel are introduced at the same end of the kiln: this prevents all possibility of overburning. The hot gases leaving the kiln are utilised for preliminary drying purposes.—F. SODN.

Barium carbonate; Preparation of — from barium sulphate. L. Pernot and E. Decamps. Fr. Pat. 394,443, Sept. 9, 1908.

A MIXTURE of barium sulphate and iron oxide (Fe_2O_3), or other appropriate oxide, in molecular proportions, is heated to redness in special retorts where it is treated with a stream of carbon monoxide and hydrogen from a gas producer. The temperature should suffice for the rapid reduction of the iron oxide, but not for melting the metal, which reduces the barium sulphate to barium sulphide and becomes re-oxidised to ferric oxide, from which the barium sulphide is separated by solution in water. Barium carbonate is precipitated from the saturated solution of the sulphide by means of the carbon dioxide produced in the reduction of the iron oxide, an excess of carbon dioxide being avoided. The retorts are heated by the combustion of any reducing gas not previously oxidised in the process.

—F. SODN.

Metallurgical [zinc, cadmium, antimony, molybdenum, etc.] sulphides and alkali thiosulphates; Preparation of — by means of "nascent" alkali sulphides. P. Pipereant and A. Vila. Fr. Pat. 394,441, Sept. 5, 1908.

THE process is for the preparation of certain metallic sulphides, such as those of zinc, cadmium, antimony, molybdenum, etc., which are usually obtained in a latitious and colloidal form. The mineral or other compound of the metal is decomposed by means of caustic alkali or alkali carbonate solution, and then powdered sulphur is added, so that alkali sulphide is produced which reacts, as formed, to give the required sulphide, the

mixture being heated until precipitation is complete. With such metals as antimony and molybdenum, the sulphide is precipitated by the addition of acid, after digesting the alkaline liquid with sulphur. The sulphides are obtained in a form well-suited to technical requirements, being dense, fine-grained, and unctuous. Alkali thiosulphate is obtained as a by-product.—F. SODN.

Gases; Process for the sudden cooling of hot — in endothermic and other reactions of gases and gaseous mixtures. Kunheim und Co. Ger. Pat. 205,774, May 9, 1907.

IN gas reactions such as the formation of oxides of nitrogen from air, it is necessary to rapidly cool the reaction products. According to the present patent, this is effected by causing a current of a suitable cooling agent, such as air or steam, to which water or solid substances (ferric oxide) in an atomised condition may be added, to pass close to the flame, thus carrying away the reaction products, and then making the two together spread out so as to form a flat stream, and thus give a large surface of contact between the reaction products and the cooling medium. Several methods are described for spreading out the current of the cooling agent carrying with it the gaseous reaction products. The process may also be applied to the preparation of formaldehyde by the incomplete oxidation of methane.—A. S.

Nitrogen from air; Process for obtaining — O. P. Hurford. Fr. Pat. 394,557, Sept. 22, 1908.

CARBONACEOUS fuel, such as coal or petroleum, is burned in sufficient air to ensure exact combustion to carbon dioxide and water. The gaseous products are then subjected to the action of water which is sprayed in at various points of an acid-proof chamber, through which the gases are made to pass in a zig-zag path, in order to condense the steam and dissolve the carbon dioxide. The process of solution may be assisted by maintaining an increased pressure in the chamber, and lime-water may be used as an absorbent. On leaving the condensing chamber, the nitrogen is purified by passing through lime-water in a further chamber, and finally it is dried by means of lime or other drying agent. Valves are provided so that the gas may be cut off from the chamber, if carbon monoxide be present in the mixture leaving the furnace.—F. SODN.

Chlorine from gaseous mixtures containing it; Process for the separation of — T. Goldschmidt. Ger. Pat. 206,104, Aug. 6, 1907.

THE gaseous mixture is passed through a liquid, anhydrous, inorganic chloride or oxychloride, not containing hydrogen, preferably stannic chloride, and the resulting liquid is exposed to diminished pressure or to increased temperature, or to both, in order to recover the absorbed chlorine. Before passing the gaseous mixture into the absorbing agent, it may be compressed almost to the point at which liquefaction of the chlorine begins.—A. S.

Ammonia; Manufacture of — J. Y. Johnson, London. From Badische Anilin und Soda Fabrik, Ludwigshafen on Rhine, Germany. Eng. Pat. 2414, Feb. 3, 1908.

VIII.—GLASS, POTTERY, AND ENAMELS.

Bottle-glass; Utilisation of rocks in the manufacture of —. Plenske. *Spezialsaal*, 1909, 42, 74—76, 88—90.

The use of crude raw materials such as rocks, slag, and dross, is recommended for the manufacture of the commoner kinds of glass. In the first place come the igneous rocks, which may contain 18 per cent. and more of alkalis, and marl, which forms a substitute for limestone. These rocks contain oxide of iron, and are therefore suitable for making the different shades of green bottle-glass. By addition of manganese or cobalt, yellow, brown, black, and blue-green tints can be obtained. The presence of alumina and magnesia in glass is important, as they improve the resistance to both chemical and physical influences. Analyses are given of various coloured glasses: (a), high in alumina and low in magnesia; and (b), those containing a medium amount of both oxides. For the first group, igneous rocks are suitable, and for the others marl or marl and igneous rocks. The great advantage lies in the high alkali-content of the rocks, which saves the expense of sodium sulphate. Analyses are given of German samples of leucitophyr, phonolite, nepheline-phonolite, trachyte, granulite, two porphyrites, syenite, and basalt, and of some marls. The best of the drosses is the so-called cobalt-sand from the working of cobalt-nickel ores, but there are important variations in its composition. Such silica, lime, and alkalis, as cannot be brought into the glass from the above rocks must be introduced as sand containing not more than 3 per cent. of alumina, chalk (95 per cent. of calcium carbonate) and Glauber salt (96 per cent. of sodium sulphate), respectively. The use of fluorspar as a flux is strongly deprecated owing to its cost, its attack on the pots, and the presence of fluorine compounds in the issuing smoke. The best flux is orthoclase. Examples are given of the method of calculating the requisite quantities of the ingredients in order to obtain a glass of given composition. —H. H. S.

Porcelain; Magnesia-cryolite —. T. Hertwig. *Tonind.-Zeit.*, 1909, 33, 181.

ALTHOUGH lime gives transparency to porcelain, its presence causes irregular shrinkage and consequent warping. Magnesia gives a greater but uniform shrinkage. Starting, therefore, with a porcelain made from 53 per cent. of clay-substance, 20 per cent. of quartz, and 27 of potash-spar, the author made an artificial magnesia-spar ($\text{MgO} \cdot \text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2$) and introduced 3.5 per cent. of it into the mixture instead of the equivalent quantity of potash-spar. Following Seger's rule that two fluxes are more powerful than one, he also introduced soda as an artificial soda-spar ($\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2$) made from cryolite. The most satisfactory mixing was—35 of Zettlitz kaolin, 20 of china clay, 21.85 of Norwegian felspar, 20 of Pleystein quartz, 1.75 of artificial magnesia-spar, and 1.4 of artificial soda-spar. —H. H. S.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

PATENTS.

Artificial stone; Manufacture of —. C. Bonnefont. Paris. Eng. Pat. 1339, Jan. 20, 1908.

A WHITE cement is first prepared, by slaking 1140 parts of "fat" lime, mixing it with 540 parts of kaolin free from iron, which has been previously soaked in water, sifting the mixture, forming it into bricks, and burning these, in a slow fire for the first 10 hours, and a hard porcelain fire for another 25 hours. The clinker is powdered, and 64 parts by volume of the cement so obtained are mixed with 36 parts of powdered white sandstone. The concrete

mixture is made into a slip of 35° B. with water, and 13 parts by volume of this slip are mixed with 6 parts of an aqueous solution of sodium silicate of 35° B. The mixture is poured into moulds of reinforced plaster lined with gelatin or plaster, and lightly greased before use. The objects are generally removed from the moulds after 3—6 hours, re-touched, and dried at 15—30° C. for 20—25 days. They are then immersed for 6—15 hours in a solution of sodium silicate of 25° B., rinsed, allowed to dry for 2 days, and immersed for one hour in a solution of hydrofluosilicic acid of 12°—15° B. The objects are finally dried for about 2 weeks at 30° C. To obtain more impermeable surfaces, the dipping in sodium silicate solution may be repeated at intervals of 5—6 days. Instead of making white stone as above, colouring matters may be added to the ingredients. —A. G. L.

Fire-bricks; Process for making —. I. Albon, Plaistow, Essex, and W. E. Parker, Bexley Heath, Kent. Eng. Pat. 24,325, Nov. 12, 1908.

EIGHT parts by volume of the powder obtained by grinding old fire-bricks are mixed with one part of fresh fireclay, one part of fine sand, and water. The paste is moulded into bricks without using any great pressure, and the bricks are dried for 10—30 days and burnt for 30—50 hours. —A. G. L.

Building stones, etc., from slag; Process of manufacture of —. Cöln-Müsener Bergwerks-Act.-Ver. Fr. Pat. 394,011, Sept. 7, 1908.

APPROXIMATELY equal quantities of slag which has been allowed to cool in air, and of slag which has been granulated in water, are ground together, with or without the addition of lime. The mass is moulded into bricks under pressure, and the bricks are hardened by treatment with carbon dioxide gas in chambers from which the air may be exhausted before the gas is admitted. —A. G. L.

Plaster of Paris; Process and apparatus for producing completely dehydrated —. J. L. F. Garrigou. Fr. Pat. 394,532, Nov. 29, 1907.

COARSE pieces of the gypsum to be burnt are placed on perforated trays contained in a perforated metal cylinder. The charged cylinder is lowered into an autoclave, provided with a cover secured by bolts. The autoclave is mounted in a brickwork chamber kept at a temperature of 200°—220° C. From the autoclave two lateral tubes, one placed near the bottom, the other near the top, pass to a worm condenser immersed in a vessel of water. This condenser delivers into a closed vessel, provided with an external glass tube by means of which the height of the water inside the vessel can be ascertained, and with a tapped tube leading to an air pump. The whole apparatus is exhausted at the beginning of the operation. The volume of water produced from the charge of gypsum being known, the amount of water condensed indicates the point at which the gypsum is completely dehydrated. —A. G. L.

Hydraulic cement. A. C. Spencer and E. C. Eckel, Washington, D.C. U.S. Pat. 912,266, Feb. 9, 1909.

THE claims are for a hydraulic cement mixture containing as principal ingredient a natural iron silicate, such as greensand, and in addition a material rich in an alkaline-earth, such as a calcareous material. —A. T. L.

Plastic compositions; Manufacture of — and of "accelerators" for the same. H. S. Spackman Engineering Co. First Addition, dated Sept. 1, 1908, to Fr. Pat. 390,194, May 13, 1908 (this J., 1908, 1021).

CALCAREOUS cements are mixed with an "accelerator," consisting of calcium aluminate, to which plaster of Paris may be added. The calcium aluminate is prepared by burning together lime and bauxite in such proportions that 3 molecules of lime are present for every 1 of alumina, sufficient lime being also provided to combine with any silica present. A suitable composition consists of slaked lime, 45 per cent.; silicious clay or shale, 45; calcium aluminate, 7; and plaster of Paris, 3 per cent. The slaked lime may be replaced by Portland cement, puzzuolana, etc. —A. G. L.

Portland cement: Manufacture of clinker for making —.
F. M. Allan. Fr. Pat. 394,189, Sept. 9, 1908. Under
Int. Conv., July 1, 1908.

WATER is supplied from distributors arranged above the kiln to the hottest part ("clinkering zone") of the metallic casing of a rotatory kiln, thus lowering the temperature of this part to that of the neighbouring portions. The excess water is conducted along a gutter to the burnt clinker issuing from the kiln. It is claimed that by using this device, the speed of working of the kiln is greatly increased, and that the firebrick lining lasts longer.

—A. G. L.

Artificial stone substances; Process for hardening calcareous — by means of carbonic acid. E. Schwanenberg and A. Rinne, Hanover, Germany. U.S. Pat. 911,547, Feb. 2, 1909.

X.—METALS AND METALLURGY.

Iron and steel; Tempering and re-heating of —.
E. Maurer. Metallurgie, 1909, 6, 33—52.

AT Osmond's suggestion, the author investigated the mechanical, physical, and chemical characteristics exhibited by pure iron (ferrite) and steels consisting wholly of austenite or of martensite, after thermal treatment. He concludes that the changes produced in the physical properties of pure iron by quenching from different temperatures are due to a deformation of α -iron, not to the formation of another allotropic modification; this conclusion is supported by the form of the curve obtained for residual magnetisation in mild steel. Further, he finds that homogeneous austenite is obtained under the same conditions as regards quenching which usually give a mixture of martensite and austenite, provided that the steel contains sufficient manganese (1.67 per cent. of manganese for 0.93 per cent. of carbon); steel containing up to 3.73 per cent. of nickel could not be converted into austenite. In steels containing but little manganese, austenite changes between 150° and 250° C. into troostite. The temperature at which the change takes place depends on the content of manganese, as shown by the physical properties (density, magnetisation, hardness) and the microscopical examination. If both austenite and martensite are present, the martensite changes first, but the rate of change is less. These observations apply only to re-heating; on cooling, austenite is converted into martensite. Hardening in liquid air acts like quenching, but in a less degree. The changes produced by quenching are due to at least two causes, one of which (the presence of temper carbon) acts on the electric conductivity, the other (probably deformation of α -iron) on the magnetisation, hardness, and density.

Osmond founds the following conclusions on the author's work: γ -iron can occur in hypo-eutectic steels as well as in hyper-eutectic steels, provided that the temperature before quenching is sufficiently high (at least 1000° C.). Hardening in liquid air also produces a small amount of γ -iron in such steels. This is shown by the small decrease in density of steel containing 0.14 per cent. of carbon at 150° C. or at 250° C. for steel with 0.4 per cent. of carbon; also by the increase or constancy of the residual magnetisation of two steels which were hardened in liquid air and then heated until a blue colour was produced. A comparison of the curves obtained for hardness and for electric conductivity

shows that no causal connection exists between the temper-carbon present and hardness; carbon can remain in solution in the steel owing to the presence of γ -iron in the martensite without producing any hardening effect. The re-heating of steel may be divided into four sharply-separated periods: From the ordinary temperature up to 150° C.; 150°–300° C.; 300°–450° C.; and 450° C. to the recalcence point. Osmond considers it likely that during the first period, 15°–150° C., the hardening carbon and its function, the electric resistance, fall rapidly; the hardness is but little changed; the residual magnetisation falls a little; the density increases owing to the disappearance of strains. During the second period, 150°–300° C., the density diminishes up to 250° C., owing to the change of γ -iron into deformed β - and α -iron, and increases again when no more γ -iron is present. The hardness also depends on the presence of the γ -iron, increasing through change of the latter to β -iron, and diminishing through the β -iron changing into α -iron. The residual magnetisation varies as the hardness, through the same causes. The electric resistance attains nearly its normal value, the change of hardening carbon into carbide being nearly complete. If no γ -iron is present, the two first periods coalesce into one period. The third period, 300°–450° C., is characterised especially by the transformation of β -iron into deformed α -iron, which, in turn, changes, but less rapidly, into crystalline α -iron. The hardness decreases rapidly, the density rises, and the residual magnetisation increases somewhat. During the last period, 450° C. to the recalcence point, the deformed α -iron changes completely into crystalline α -iron, and the individual molecules of carbide previously produced form aggregates. The hardness attains its normal value. The density falls, probably owing to the agglomeration of the carbide molecules having more effect than the crystallisation of the α -iron. The residual magnetisation diminishes owing to both causes. The above four intervals of temperature may probably serve to characterise the respective domains of martensite, troostite, sorbite, and pearlite.—A. G. L.

Malleable cast iron; Preparation of —. F. Giolitti, F. Carnevali, and G. Gherardi. Atti R. Accad. dei Lincei, Roma, 1908, [5], 17, 11, 662–667, 748–754. Chem. Zentr., 1909, 1, 695–696.

PIECES of cast iron containing 2.9–3.6 per cent. of carbon, 0.1–0.2 of silicon, and 0.03–0.18 of manganese were cleaned, surrounded with a mixture of oxides of iron, and heated at about 1000° C. After different periods the carbon content was determined at different depths, and test-pieces were also examined microscopically. It was found that the carbon content mostly changed gradually according to the depth; only in the neighbourhood of 0.9 per cent. of carbon was the curve somewhat steeper than with lower or higher proportions of carbon. In the authors' opinion there is always a pearlite zone of constant composition (compare Wüst, this J., 1908, 450) between the layers of hypo- and hyper-eutectic iron in which the carbon content changes gradually according to the depth. The diffusion of the oxidising gases from the iron oxides into the interior of the cast iron is a much more potent factor in decarburisation than the diffusion of carbon from the interior outwards. The layer of pure ferrite on the exterior of the metal is not produced from the iron oxides as stated by Wüst, but by the complete decarburisation of the outermost layers of the cast iron; pure ferrite is also produced in the interior of the metal on the bounding surfaces of cracks and fissures. The iron reduced from the oxides is spongy. The formation of the almost completely decarburised outer layer shows how much more rapidly the oxidising gases penetrate inwards than the carbon diffuses outwards.—A. S.

Iron; The rusting of —. G. T. Moody. Chem. Soc. Proc., 1909, 25, 34.

THE author considers that in the experiments described by Tilden (this J., 1908, 941), that author has lost sight of the well-known fact that commercial iron and steel invariably contain foreign substances, notably sulphur compounds, which on exposure to air and water at once furnish free

acids. The rusting observed in Tilden's experiments, in which carbonic acid was excluded, was a result primarily of interaction between acids, formed by oxidation of sulphur compounds and other foreign constituents capable of furnishing acids on reaction with water and oxygen, and iron, the resulting ferrous salt being subsequently oxidised with production of rust. Tilden's experiments conclusively show that commercial iron after treatment with chromic acid no longer rusts in presence of water and oxygen, but the inactivity is wrongly attributed to the chromic acid rendering the iron "passive." The true explanation of the inhibitive effect of chromic acid is that it removes from the surface of the iron those constituents which would otherwise subsequently yield acids on exposure to water and oxygen. That Tilden's view that the iron is rendered passive is incorrect is shown by the readiness with which the iron rusts as soon as normal air containing carbonic acid or any other acid is admitted. Tilden further states that after immersion for years of iron in dilute chromic acid, he has observed "no sign of rust or of dissolution of the iron either by change of colour or the formation of precipitate on adding excess of ammonia." In this connection it must be pointed out that ferric hydroxide is readily dissolved by chromic acid, so that visible change could not be expected. Moreover, dilute solutions of iron in chromic acid do not afford a visible precipitate or a change of colour on addition of excess of ammonia. If, however, the solution is filtered after addition of ammonia, ferric hydroxide in appreciable quantity remains on the filter-paper, and the dissolution of the iron is thereby made evident.

Thermite process. [Copper]. W. Skinder. Bull. Acad. St. Petersburg, 1908, 97-102. Chem. Zentr., 1909, I, 629.

THE reaction expressed by the equation, $3\text{CuO} + 2\text{Al} \rightarrow 3\text{Cu} + \text{Al}_2\text{O}_3$, is accompanied by a development of heat amounting to 650 cals. per kilo. of the mixture.—A. S.

Copper coinage alloys; Change of structure of — by thermal and mechanical treatment. F. Giolitti and E. Pannain. Atti R. Accad. dei Lincei, Roma, 1908 [5], 17, II, 668-670. Chem. Zentr., 1909, I, 696.

THE authors describe the method of treating the metal in the manufacture of bronze coins in Rome. The plates of metal are reduced in thickness from 7-8 mm. first to 1.5, then to 1, and finally to 0.7 mm. by heating, quenching, and repeated rolling. The alloy used by the authors contained 95.8 per cent. of copper, 3.82 of tin, and about 0.2 of lead. In the normal condition it consisted of patches of a solid solution (α) separated by crystals of a second solid solution (β). The repeated alternate heating and rolling of the alloy caused a change of structure, until finally the compression exerted in the stamping operation broke the crystals (α and β), and a finely-crystalline granular structure resulted.—A. S.

Magnetic manganese alloys. X. Manganese-aluminium-copper. F. Heusler and F. Richarz. Z. anorg. Chem., 1909, 61, 265-279.

THE magnetic properties of manganese-copper-aluminium alloys depend upon the aluminium-content and the condition of the alloy. Manganese-aluminium-bronzes (see this J., 1906, 318) when quenched from a red heat in cold water or mercury are non-magnetic. If, however, they are "aged" by keeping in boiling toluene or more rapidly (in a few hours) in boiling xylene, the magnetic properties quickly increase to a maximum value, and after this treatment the alloys show practically no hysteresis. If the alloys be cooled slowly from a red heat, they are magnetic, and the magnetic properties increase to about the same extent on "ageing" as in the case of the quenched alloys, but the slowly-cooled and "aged" alloys exhibit strong hysteresis depending upon the rate of cooling. The alloys are thus capable of existing in three conditions: (1), the labile slightly magnetic; (2), the strongly magnetic with practically no hysteresis; (3), the strongly magnetic with strong hysteresis. Experiments as to the influence of the composition of the alloys on the magnetic properties gave results from which and from other data the following conclusions are drawn:—Copper

and aluminium form a compound, AlCu_3 ; manganese and copper form a series of mixed crystals containing up to about 30 per cent. of manganese. In the compound, AlCu_3 , copper can be replaced by manganese to give compounds, $(\text{AlMn})_3\text{Cu}$, in which M_3 represents an isomorphous mixture of copper and manganese, and it is to such compounds the magnetic properties of the manganese-aluminium-copper alloys are attributed. (See also this J., 1904, 985; 1905, 850, 1237.)—A. S.

Magnetic alloy; Heusler's —. R. Jack and A. D. Ross. Proc. Roy. Phil. Soc., Glasgow, 1907-1908, 39, 41-46. (See this J., 1904, 985; 1905, 850, 1237; 1906, 318, and preceding abstract.)

THE authors have investigated the magnetic properties of an alloy consisting of 25 per cent. of manganese, 12.5 of aluminium, a trace of lead, and the remainder of copper. It was found that in the alloy in the normal condition, at least, the hysteresis was small and the saturation well marked. On heating the alloy at gradually increasing temperatures, the magnetic quality gradually improved up to 160° C., but heating at temperatures above this caused deterioration, with marked increase in hysteresis. The magnetic quality was improved most by immersing the alloy in liquid air, but it returned to its former condition when the alloy was again brought to the ordinary temperature. Quenching lessened the hysteresis, but with increasing temperatures, up to 610° C., gradually destroyed the magnetic quality. There was a well-defined minimum at 610° C. and by quenching from higher temperatures, the magnetic quality was to a considerable extent restored. The condition at the normal temperature appeared to be the stable one.—A. S.

Metallic nickel; Absorption of hydrogen by —. A. Sieverts and J. Hagenacker. Ber., 1909, 42, 338-347.

THE results of Mayer and Altmayer (this J., 1908, 1116) differ so greatly from those obtained by Sieverts and Beckmann in 1907, that the authors have repeated and extended Sieverts and Beckmann's observations, using the same small quantity of nickel as Mayer and Altmayer, and using both the nickel used in 1907, and also some prepared by themselves by reducing the oxide at as low a temperature as possible. They still find that at the atmospheric pressure 1 volume of nickel absorbs from 0.15 volume of hydrogen at 212° C. to 0.9 volume at 923° C. At 923°, and also at 822°, the volumes of gas absorbed at different pressures are proportional not to the pressures, but to their square roots, so that the hydrogen would appear to exist in the metal in the half-molecular, or atomic condition.—J. T. D.

Chromium mineral [chromitite]; A new — in Servia. M. Z. Jovitschitsch. Monatsh. Chem., 1909, 30, 39-46.

THE new mineral is a fine grained glistening sand, composed of dark and light particles, found in the streams on the sides of Mt. Zelin in Servia. The dull dark particles comprise about 2 per cent. of the whole; they are magnetic and easily separated by means of a magnet. The glistening crystals are very hard; they are not dissolved by mineral acids and are difficult to convert into chromates by the usual fusion method. They are fused with a mixture of 1 part each of sodium and potassium carbonate, and $\frac{1}{2}$ parts of lime. They have the composition, FeCrO_3 , and represent a chromic oxide in which one atom of chromium is replaced by iron—traces of aluminium and magnesium are regarded as impurities. The new mineral, which is thus different from ordinary "chromite" ($\text{FeO} \cdot \text{Cr}_2\text{O}_3$), is named *chromitite*. The dull magnetic crystals may be classified into fractions of different magnetic power: they contain 43 to 45 per cent. of iron and 21.5 to 25 per cent. of chromium, and are regarded as a double compound, $2\text{Fe}_2\text{O}_3 \cdot \text{Cr}_2\text{O}_3$.—E. F. A.

Calcium sulphate; Behaviour of — at elevated temperatures with some fluxes. H. O. Hofman and W. Mostowitsch. Bull. Amer. Inst. Mining Eng., 1909, Jan., 25-76.

THE authors have investigated the causes of the behaviour of gypsum when used in the blast-roasting of lead sulphide

ores and in other metallurgical operations. Anhydrous calcium sulphate commenced to decompose at about 1200° C., oxygen and sulphur dioxide being evolved. The material fused at about 1360° C., but was not entirely decomposed even when heated to 1400° C. Pure silica was mixed with calcium sulphate in the proportions to form mono-, di-, and tri-silicates, and heated. In each case sulphur dioxide was given off at about 1000° C., and decomposition was complete at about 1300° C., the whole of the lime and silica combining to form silicates. Pure ferric oxide sinters at 1500° C., but remains chemically unchanged. The addition of 25 per cent. of magnesia does not affect this result. A mixture of molecular proportions of calcium sulphate and ferric oxide fuses at 1250° C. with partial decomposition, oxygen and sulphur dioxide being evolved, and on continuing the heating at the same temperature for 15 minutes, complete decomposition ensues, calcium ferrite, $\text{CaO} \cdot \text{Fe}_2\text{O}_3$, being formed. Tests were also made with calcium sulphate and pure lead oxide; the calcium sulphate remained unaffected, but the lead oxide was rapidly volatilised, about 50 per cent. having been lost when a temperature of 1200° C. was attained. These tests show that gypsum added to a raw lead sulphide ore is decomposed, mainly by silica and ferric oxide, with evolution of sulphur dioxide, and has no decomposing effect on the galena, which is oxidised only by the air blast. In the case of ordinary roasting, the temperature is not raised sufficiently to decompose the gypsum, which therefore remains and increases the percentage of sulphur in the roasted charge. When roasting calcareous blends, the calcium carbonate is converted into sulphate, which is decomposed at about 1200° C. owing to the presence of silica and iron oxide. In consequence of the resistance of magnesia to combination with ferric oxide, a highly magnesian dolomite forms a more refractory lining to converters when the slag is very basic.—F. R.

Limit of elasticity: Determination of — by a thermoelectric method. A. Dinnik. J. Russ. Phys.-Chem. Ges. 1909, 40, Physik. Teil., 335—339. Chem. Zentr., 1909, 1, 421.

The mechanical extension of a metal bar is accompanied by a development of heat, the amount of which is proportional to the tensile force exerted. So soon as the limit of elasticity is exceeded, however, there is a sudden rise of temperature, so that by aid of a sensitive thermocouple, this point can be easily determined.—A. S.

Iron ore: Process of treating —. C. B. Morgan, Oakland, Cal. U.S. Pat. 910,707, Jan. 26, 1909.

IRON ore mixed with a flux is heated in a furnace until molten, and sufficient carbonaceous matter in the liquid state is then added to reduce the iron.—A. G. L.

Iron and steel: Process of manufacturing —. C. Ellis, White Plains, N.Y. U.S. Pat. 911,870, Feb. 9, 1909.

THE iron oxides to be reduced are passed through a reverberatory furnace on an endless band beneath a luminous flame, produced by a blast of air and powdered coal, which plays along the roof of the furnace. The oxides are shielded from direct contact with the luminous flame by a current of reducing gas, for example producer gas, which travels in the opposite direction to the oxides and to the luminous flame, and gradually becomes a flame merging with the latter.—A. T. L.

Precious metals: Ammonia-cyanide process of treating ores containing —. D. Mosher, Assignor to Ammonia Cyanide Eng. Co., San Francisco, Cal. U.S. Pat. 911,254, Feb. 2, 1909.

ORES and tailings containing gold and silver are extracted with a solution of ammonia and an alkaline-earth cyanide. If the ores or tailings contain copper, nickel, zinc, or cobalt as well as gold and silver, all the metals are extracted together by this process.—A. T. L.

Crucible furnace. E. H. Schwartz, Assignor to Kroeschell Bros. Co., Chicago, Ill. U.S. Pat. 911,271, Feb. 2, 1909.

THE furnace is provided with a concave crucible seat surrounded by a gutter having an outlet for the discharge of slag. The heating gases are admitted tangentially into the base of the furnace chamber, so as to circulate around the crucible, and air is admitted into the path of the heating gases through ducts passing diagonally through the walls into the gutter at two opposite points.—A. T. L.

Lead and zinc: Process of treating complex sulphide ores of —. E. Vuigner, First Addition, dated Nov. 11, 1907, to Fr. Pat. 381,038, Oct. 26, 1906 (this J., 1908, 129).

COMPLEX zinc ores are roasted, mixed with sufficient carbon to reduce the sulphates formed, and with a flux, e.g., fluorspar, and charged into a bath of molten iron. The zinc produced by the action of the carbon and of the iron (in presence of the silica of the ore) reduces the other metals, e.g., gold, silver, copper, lead, and antimony, present in the complex ores.—A. G. L.

Zinc: Process of extracting — from zinc sulphide ores, especially from those containing copper. E. Vuigner, First Addition, dated Nov. 12, 1907, to Fr. Pat. 381,039, Oct. 26, 1906 (this J., 1908, 129).

THE zinc ore is directly charged into a converter containing a fused sulphide, e.g., of copper or iron. The process consists in removing the sulphur by blowing in air, and reducing and volatilising the zinc by means of carbon.—A. G. L.

Converter with readily removable body and lateral introduction of air. A. Zenzes. Fr. Pat. 394,263, Sept. 14, 1908.

AIR is supplied from a hollow wind-box to a number of horizontal tuyères which traverse the lining of the converter. The wind-box is not fastened to the converter, but is kept in place by a flange on the latter. Before removing the converter for repairs, the wind-box with its attached tuyères is pulled away from the converter.

—A. G. L.

Alumina: Reduction of —. O. Serpek. Ger. Pat. 206,588, Feb. 15, 1908.

THE reduction of alumina by means of carbon can be effected only with difficulty and by the use of a very large expenditure of heat. Moreover the yield is low, because at the high temperature employed, alumina and aluminium are lost by volatilisation, and the carbon monoxide produced reacts with the aluminium with re-formation of alumina. In order to avoid these difficulties, according to the present patent, compounds of barium or of strontium, or both, are added to the charge. For example, a mixture of 40 parts of alumina, 4 parts of baryta, and 14 parts of carbon is heated in an electric arc furnace. The reaction product contains 60—70 per cent. of aluminium, of which one-half is present as metal, and the remainder as aluminium carbide. The consumption of energy amounts to about 5 kilowatt-hours per kilo. of aluminium (as metal and carbide) in the reaction product.—A. S.

Cyanide process for extracting precious metals from their ores and apparatus for carrying out such process. H. Birkbeck, London. From Just Mining and Extraction Co., Syracuse, U.S.A. Eng. Pat. 1582, Jan. 23, 1908.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

(I.)—ELECTRO-CHEMISTRY.

Borates: Some electrolytically prepared —. M. G. Levi and S. Castellani. Atti R. Accad. dei Lincei, Roma, 1908, [5], 17. II., 613–617. Chem. Zentr., 1909, I., 594.

In the authors' experiments the cathode and anode compartments were separated by a diaphragm, and contained respectively a solution of boric acid and a solution of a salt of the metal of which it was desired to obtain the borate. With a 10 per cent. solution of an alkaline-earth chloride and a saturated solution of boric acid, using a current strength of 0.5–1 ampère, there were obtained in the first hour precipitates of fairly constant composition, $\text{Ca}(\text{Ba}, \text{Sr})\text{O} \cdot \text{B}_2\text{O}_3 \cdot 4\text{H}_2\text{O}$, at the cathode. Subsequently, or on addition of alcohol, precipitates richer in boric acid but of less constant composition were obtained; in the case of calcium, however, the composition ($\text{CaO} \cdot 2\text{B}_2\text{O}_3$) was fairly constant. With magnesium salts, the borate precipitated in the first stage of the process was strongly contaminated by oxide; after the electrolysis, a salt of approximately the composition, $3\text{MgO} \cdot 4\text{B}_2\text{O}_3$, was precipitated from the solution by alcohol. Attempts to prepare borates of heavy metals electrolytically proved unsuccessful.—A. S.

Electrical migration of invertase. Michaelis. See XVII.

PATENTS.

Cells: Electrolytic —. A. E. Gibbs, Wyandotte, Mich. U.S.A. Eng. Pat. 28,147, Dec. 17, 1907.

In electrolytic cells of the kind described in Eng. Pat. 27,830 of 1907 (this J., 1908, 80), the closed anode chamber is provided with a float for showing the level of the liquid. A vertical transparent tube, open at its lower end and closed at the top, passes through the cover of the cell, so that it extends partly within and partly outside the cell, and the stem of the float projects into this tube.

—B. N.

Furnaces: Electric —. The British Thomson-Houston Co., Ltd., London. From the General Electric Co., Schenectady, N.Y. Eng. Pat. 1470, Jan. 21, 1908.

The object of the invention is to provide an electric tube furnace capable of use at temperatures as high as that at which carbon begins to be vaporised, without any danger of the material under treatment being contaminated with carbon. A resistance tube of refractory metal, such as tungsten, or a mixture of tungsten and thorium, is used as the heater, with a refractory non-carbonaceous packing, such as calcium oxide, alumina, thorium, etc., surrounding the tube. Outside the hot zone, the packing material may be surrounded by carbonaceous material, such as coke. Hydrogen, or some other inert gas, is passed through the packing to prevent deterioration of the exterior of the heater.—B. N.

Furnaces: [Electric] —. M. Ruthenburg, Lockport, N.Y., U.S.A. Eng. Pat. 12,498, June 9, 1908.

The furnace comprises a stationary upper casing, and a removable hearth forming a floor to the casing. The hearth may be raised or lowered by hydraulic means, and may be retained in position, after raising, by the employment of wedges. The hearth is provided with wheels, so that, when lowered, these engage with a suitable track for moving the hearth into a position for discharging its contents into a conveyor. The electrodes are supported in the chamber, which is open to the atmosphere, by means independent of both the furnace casing and the hearth.—B. N.

Electrodes of electric furnaces: Connections for the —. C. A. Keller, Paris. Eng. Pat. 12,634, June 12, 1908.

The head of the electrode is provided with an undercut recess, into which is inserted the dovetail end of a conductor, the latter consisting of a hollow copper core surrounded by a hollow cast iron or steel sheath. The sheath is provided with recesses or grooves, and molten metal, preferably copper, is poured in so as to fill these and the space between the electrode and the conductor, the metal making direct electrical connection between the electrode and the internal copper core. Water is circulated through the hollow copper core, for the purpose of cooling.—B. N.

Furnace: Electric —. J. H. Reid, Newark, N.J. U.S. Pat. 910,581 and 910,582, Jan. 26, 1909.

(1). The electrodes, for producing the arc, are provided with automatic constant current regulators, and with neutral conveying resistance elements having contracting ends extending between the ends of the electrodes. The resistance elements and the electrodes constitute a crucible for supporting the charge, and the former at the same time afford resistance to the passage of the current. (2). A polyphase current is employed, and the furnace is provided with several converging electrodes, having different phases of the current flowing through each. A vertical electrode, adapted to extend into the top of the charge, is connected to the neutral point of the polyphase system, and each of the electrodes is provided with an automatic constant current regulator.—B. N.

Chemical compounds (sodium oxides): Process of manufacturing — [electrolytically]. C. F. Carrier, jun., Elmira, N.Y. U.S. Pat. 910,498, Jan. 26, 1909.

COMPOUNDS of the alkali and alkaline-earth metals, such as sodium oxides, are obtained by continuously producing an alloy of sodium by the electrolysis of a fused bath containing metallic sodium, with a fluid cathode comprising a metal which is electronegative to sodium. The alloy thus formed is used as a fused soluble anode, the electrolyte consisting of approximately two parts of melted sodium nitrate and three parts of caustic soda, which react with the sodium of the alloy to form the desired oxide.—B. N.

Electrolytic apparatus. P. Borgnet. Second Addition, dated Sept. 14, 1908, to Fr. Pat. 377,249, April 29, 1907 (this J., 1907, 1054; 1908, 757).

THE transverse displacement of the floating cathode is prevented by guiding each extremity between two vertical rods, and the descent of the cathode below a certain point is avoided by means of a horizontal rod placed between the vertical rods.—B. N.

[Electric] Pile, with zinc and lead, and three neutral liquids. A. Sarrette. Fr. Pat. 394,123, Nov. 18, 1907.

NEGATIVE electrodes of zinc and positive electrodes of copper or lead are placed in separate porous vessels, arranged alternately in an outer bath. The negative electrode is immersed in a solution of zinc sulphate (20° to 25° B.), the positive electrode in a solution of copper sulphate (24° to 35° B.), and the porous vessels in a solution of sodium sulphate (20° to 30° B.). The porous vessels are constructed of an impermeable wood frame, with horizontal or vertical bars of wood or twine for supporting the envelope, the frame being covered with

parchment paper fastened to the wood, and enclosed in muslin. The positive electrode is made in the form of a perforated copper or lead vessel, divided by a perforated inclined wood partition into two compartments, one of which contains crystals of copper sulphate. This vessel is placed in the porous vessel containing the solution of copper sulphate, the large surface of the electrode diminishing considerably the internal resistance. The zinc sulphate and sodium sulphate solutions are introduced through funnels attached to tubes, the latter reaching to within a few centimetres of the bases of the respective vessels.

—B. N.

Ozone; Apparatus for the production of — by means of electric discharges. J. Steynis. Fr. Pat. 394,124. Nov. 18, 1907.

A LIQUID, produced by compression of a gas, is circulated through hollow electrodes, and the heat produced by the discharges is thus employed for the evaporation of the liquid. The resulting gas is again compressed in order to convert it into the liquid condition for further use.

—B. N.

Carbides; Process for the preparation of — by induction heating. G. Erlwein and V. Engelhardt. Ger. Pat. 206,175, July 9, 1907.

THE patent relates to the application of the electric induction furnace to the manufacture of calcium carbide. The charge itself forms the secondary, and the initial heating is effected by embedding closed rings of carbon in the charge, or by placing closed rings of molten or solid calcium carbide on the bottom of the fusion-trough of the furnace.—A. S.

Electric accumulators; Process of agglutinating active material for —. Q. Marino and E. W. Barton-Wright, London. U.S. Pat. 911,141, Feb. 2, 1909.

(B.)—ELECTRO-METALLURGY.

PATENTS.

Titanium alloys; Process of making —. F. M. Becket, Niagara Falls, N.Y., Assignor to Electro Metallurgical Co., New York. U.S. Pat. 910,894, Jan. 26, 1909.

CHARGES containing titanium oxide and silica are continuously reduced by means of carbon in an electric furnace, so much silica being present that the product obtained shall contain not more than 10 per cent. of carbon.—A. G. L.

Copper; Extraction of — electrolytically from solutions containing the metal in the form of sulphate, chloride, or other salt. J. B. M. E. Vuigner. Fr. Pat. 393,968, Nov. 12, 1907.

ONE or more cathodes of copper and one or more anodes of iron are connected by an external conductor, and immersed in a solution of the copper salt. An external auxiliary electric current may be employed in addition.

—B. N.

Scouring and cleaning of small [metal] objects; Process for the electrolytic —. A. Lévy. Fr. Pat. 394,120, Nov. 13, 1907.

IN the removal of grease (scouring) and of oxide (cleaning) from metal objects by means of hydrogen liberated in an electrolytic bath, there is difficulty in effecting electrical contact with a large number of small articles. According to the present patent, the objects are placed in bulk in a basket or cage, or other appropriate receptacle, and

immersed in a suitable electrolytic bath. The basket is constructed of a metal, such as tin, zinc, or aluminium, preferably aluminium for scouring and zinc for cleaning, which is attacked by the electrolyte, and thus causes liberation of hydrogen.—B. N.

XII.—FATTY OILS, FATS, WAXES, AND SOAPS.

Oils and oil seeds; Some African —. Bull. Imp. Inst. 1908, 6, 353—380.

THE results of the examination of specimens of the following African oils are given:—(1). Non-drying oils: ground-nut, "ikpan" seed, "inoy" kernel, "ben" seed, carapa seed, *Calodendron capense*, *Balanites aegyptiaca*, and "zawa" ("niam") oils. (2). Drying oil: *Ricinodendron Heudelotii* (*R. Africanum*) ("Nsa-sana") seed oil. (3). Solid or semi-solid fats: "shea" butter, fat from seeds of *Mimusops* sp., fat of "dika" nuts, *Pentadesma butyracea* fat, fat of "mafoureira" nuts, fat of *Pycnanthus* seeds. Several of these oils and fats have been examined previously (see this J., 1903, 751; 1904, 233, 793; 1906, 1159; 1907, 623, 976; 1908, 511, 758, 819, 1161; also Lewkowitsch, this J., 1904, 25; 1906, 30; 1907, 1265; 1908, 578; 1909, 150).

Ground-nut oil from Northern Nigeria had the usual characters, but owing to its slight peculiar odour and taste would be suitable only for soap-making.

Samples of the oil from *Balanites aegyptiaca* seeds were received from (1), Northern Nigeria ("betu" oil) and (2), the Sudan ("heglig" seeds). The kernels from the former source yielded 58.7 and those from the latter, 41 per cent. of oil. The oils had the following characters: sp. gr. at 15° C. 0.919, 0.9187; acid value, 5.0, 1.4; saponification value, 196.7, 194.2; iodine value, 92.5, 98.2; Hehner value, 95.2, 98.6; Reichert-Meissl value, (2), trace; unsaponifiable matter, (1), about 0.6 per cent.; titer test, about 34.6° C. 34° C. The oil consists of about 33 per cent. of olein, 33 of linolin, and 34 of stearin and palmitin.

Specimens of shea nuts were obtained from Northern and Southern Nigeria, the Gold Coast, and the Sudan. The yield of fat from the kernels ranged from 41.4 to 54.5 per cent. The fat ("shea butter") had the following characters:—Sp. gr. at 99°—100°/15°—15.5° C. 0.8594—0.8691; acid value, 7.6—33.9; saponif. value, 179—184.6; iodine value, 54—62.9; Hehner value, 91.2—96.5; Reichert-Meissl value, 1.4—2.6; unsaponifiable matter, 1.7—7.0 per cent.; titer test, 51.8°—53.2° C. Shea butter is used in the manufacture of candles and, to some extent, for soap-making; it is also said to be used for the manufacture of butter substitutes. For the candle and soap industries, it is worth about £24 5s. to £24 10s. per ton.

The kernels from the nuts of a species of *Mimusops*, probably *M. djave*, from Southern Nigeria, yielded 60.2 per cent. of a fat closely resembling shea butter in character.

Pentadesma butyracea fat from Sierra Leone had the sp. gr. at 100°/15.5° C. 0.859; acid value, 3.6; saponif. value, 190.1; iodine value, 41.8; Hehner value, 95.0; Reichert-Meissl value, nil; unsaponifiable matter, 1.7 per cent.; titer test, 50.7° C. The fat would perhaps be useful as an edible fat and for the manufacture of candles.

Specimens of fruit, seeds, and "mace" from *Pycnanthus* sp. from Northern Nigeria and Uganda were examined. (1). The seeds obtained from Nigeria resembled nutmegs, but contained no volatile oil; the kernels yielded 54 per cent. of an orange-coloured bitter fat. (2). The kernels from Uganda yielded 60.2 per cent. of a dark-brown, slightly bitter fat. These fats had the following characters:—Sp. gr. at 99°—100°/15° C. 0.886, 0.887; (1), m.p.t., 48.5°; saponif. value, 235—245, 255; acid value, 21, 16.5; Hehner value, 90.8, 90.9; iodine value, 48.9, 65.4; titer test, 45.8°, 37° C. The fat might be used for soap-making and for the manufacture of candles, but would need decolorising. The "mace" from Uganda yielded 57.04 per cent. of oil, which however was dark-coloured, and could not be decolorised without heavy losses.—A. S.

Maumené value of oils and fats; Determination of the —.
M. Tortelli. Chem.-Zeit., 1909, 33, 125—126, 134—135, 171—172, 184—185.

It was found by Mitchell (this J., 1901, 931) that the Maumené values obtained by dissolving the fat in carbon tetrachloride in a vacuum-jacketed tube and adding the sulphuric acid to the solution, were in most cases proportional to the iodine values. The author here shows by a long series of parallel results that this relationship between the two values may also be observed when an oil is treated in a vacuum-jacketed tube with the sulphuric acid directly (see this J., 1904, 668). In the case of solid fats the substance is melted before the addition of the acid and the specific heat of the reacting bodies taken into consideration. The ratio between the Maumené figure and the iodine value decreases with the iodine value. Thus, in the case of four samples of butter the ratio varied from 1.03 to 1.06, whilst with four samples of margarine it ranged from 1.33 to 1.49, and with four samples of cocoanut oil from 0.31 to 0.34. The method is therefore recommended as a useful means of detecting foreign fats in butter.—C. A. M.

Oleic acid; Action of ozone on —. C. Harries. Ber., 1909, 42, 446—458.

ACCORDING to Molinari (this J., 1908, 1073) ozonised air containing only a small percentage of ozone converts oleic acid into a different ozonide from that formed by air containing more ozone; otherwise it is not possible to explain the differences in their decomposition-products. The author, however, finds that this is not the case, and that the same normal oleic acid ozonide, $C_{18}H_{34}O_5$, is obtained by ozonisation of the oleic acid in different solvents with ozonised air containing different percentages of ozone, or by washing the perozonide with sodium bicarbonate solution and water. Oleic acid ozonised by oxygen containing 0.4 per cent. of ozone gave the normal ozonide with the same properties as already described (this J., 1906, 1158). Molinari (*loc. cit.*) found that the normal ozonide did not yield hydrogen peroxide on treatment with water, but the author identified that compound by three tests, including that of Arnold and Mentzel used by Molinari. The ozonide obtained by treatment with oxygen containing over 12 per cent. of ozone had the same properties, and also yielded hydrogen peroxide on treatment with water. The same reaction was also given by the normal ozonide derived from the perozonide of oleic acid (this J., 1906, 1158). The decomposition of the normal ozonide by water is monomolecular, the products containing only 9, and not 18 atoms of carbon. Acids containing 18 atoms of carbon are only obtained by boiling the ozonide with aqueous or alcoholic potassium hydroxide solution, followed by treatment with steam. The primary products of the decomposition are aldehydes and their peroxides, *viz.*: (a) nonylaldehyde and the peroxide of the semi-aldehyde of azelaic acid; or (b) nonylaldehyde peroxide and the semi-aldehyde of azelaic acid. The peroxides of the aldehydes are decomposed by water, being transformed partly into aldehydes and hydrogen peroxide, and partly into isomeric acids (see also this J., 1906, 1055).—C. A. M.

Raphia wax. Bull. Imp. Inst., 1908, 6, 380—383. (See this J., 1906, 433; 1907, 420; 1908, 987.)

IN an experimental trial with ten raphia palm leaves, the yield of wax was 0.75 per cent. of the weight of the leaves, or about 17 per cent. of the weight of dry fibre from the leaves; in practice the yield would probably be about 10 per cent. of the weight of the fibre. Two samples of the wax were examined, with the following results: sp. gr. at 99°/15.5° C., 0.836, 0.832; acid value, 4.9, 6.5; saponification value, 51.3, 50.3; iodine value, 7.68, 10.7; m.p., 82°, 83° C. It is stated that the cost of production, etc., of the wax, cannot be reduced below £80 per metric ton f.o.b. Yamatave, Madagascar; hence it is too dear for use in the manufacture of soap and candles. A good supply of the wax of pale colour and free from grit, at the price mentioned, might however find considerable use as a substitute for carnauba wax.—A. S.

Fatty acids ("total fatty matter") in soap; Determination of —. G. Fendler and L. Frank. Z. angew. Chem., 1908, 22, 252—261.

FROM a systematic study of the different methods proposed for the determination of the fatty acids in soap, the authors conclude that in the case of cocoanut and palmnut oil soaps the only exact method is to weigh the fatty acids in the form of alkali salts. For factory control they recommend Lüring's apparatus, in which the volume of fatty acids is read directly on a scale, as sufficiently satisfactory. For linseed oil soaps Hehner's method gives good results, as do also the methods in which the liberated fatty acids are shaken out with ether or petroleum spirit and the extract evaporated, provided that the residue is dried in a current of carbon dioxide. The ordinary method of liberating the fatty acids and weighing the cooled melted layer (after the addition of wax if required) is only suitable for control purposes. Alkali salts obtained from linseed oil soaps increase in weight when dried in the air. Determination of the fatty acids in the form of calcium salts and the use of Lüring's apparatus give unreliable results with these soaps. The fatty acids in olive oil and tallow soaps may be satisfactorily determined by Hehner's method or the extraction methods, and may be dried in the air. Determination of the fatty acids in the form of calcium salts is unreliable for tallow, but approximately correct for olive oil. Lüring's volumetric method is not applicable to fats of high m.p. (tallow), but gives approximately correct values with olive oil soap.—C. A. M.

Denaturation of cottonseed, china, kapok seed, and rape seed oils for illuminants. Australian Customs Order. Board of Trade J., Feb. 18, 1909. [T.R.]

A CUSTOMS ORDER (No. 1,083 of 1908) dated 19th December last, directs Collectors of Customs to give publicity to the following requirements as to the method of denaturation of cotton seed, china, kapok seed, and rape seed oils, when for use as illuminants, in the Australian Commonwealth:—

To each 100 gallons of the oil add the following, *viz.*:—20 galls. of high test kerosene, 3 galls. of commercial cod oil, and 1 gall. of thin residual oil of sp. gr. not above 0.90 at 60° F., flash-point not below 150° F.; and viscosity not above 1 min. 50 sec. at 80° F. (Redwood). The denaturants must be submitted for approval to an official analyst and the denaturation must take place in the presence of an officer.

PATENTS.

Lubricating oils with a basis of castor and mineral oils; Preparation of —. E. Boyer, L. Cavaillon, and N. Barisbae. Fr. Pat. 391,992, July 3, 1908.

CLAIM is made for a process of heating castor oil with acids, or anhydrides or chlorides of mineral or organic acids (*e.g.*, with 4 per cent. of acetic acid), so as to obtain products readily soluble in mineral oils.—C. A. M.

Fat from the bodies of animals; Method and apparatus for separating, sterilising, and clarifying —. Actien Maschinenbau-Anstalt, vorm. Venuleth und Ellenberger. Fr. Pat. 394,076, Sep. 9, 1908. Under Int. Conv., Feb. 13, 1908.

THE fat is separated partially or completely by means of steam, hot air, gas, or hot liquids, but preferably by means of the gelatinous aqueous decoction coming from the extractor, whilst at the same time the top of the separator is heated by steam also derived from the extractor. The apparatus is so arranged that the fat is kept apart from the ammoniacal vapours. In a special apparatus claimed for this purpose, the animal material is heated by means of steam under pressure in a closed upper tank. The aqueous decoction (carrying the fat) passes through a pipe at the bottom into a separator divided into two chambers. The fat rises into the inner chamber, which is heated at the top by steam conveyed from the extractor. The two chambers communicate at the top by means of a pipe provided with a tap, so that the pressure within both may be equalised, while still

leaving an upper cushion of pure air above the melted fat. This prevents the ammoniacal vapours coming from the extractor rising to any material extent into the inner chamber and contaminating the fat during its clarification and sterilisation.—C. A. M.

Fish oils and fats; Process for deodorising —. C. H. J. Wellimg. Fr. Pat. 394,456, Nov. 26, 1907.

THE oil to be purified is emulsified with alcohol, jets of the oil and alcohol being caused to impinge against each other for this purpose. After removing the portion of the alcohol which separates out, the oil is washed with hot water in order to recover that part of the alcohol which is held in suspension in the oil. The washed oil may then be treated with fuller's earth or animal charcoal. —W. P. S.

Fish oil; Process for deodorising —. G. van der Heyden. Fr. Pat. 394,530, Nov. 29, 1907.

THE oil is introduced into a vertical cylinder and heated to a temperature of 40° C. by means of a steam- or water-jacket surrounding the cylinder. Alcohol is then injected at the bottom of the cylinder, the quantity employed being about six or eight times the volume of the oil, which at the commencement of the operation should about three-quarters fill the cylinder. The alcohol rising to the top of the oil is run off into a separate vessel and when sufficient alcohol has been injected, the temperature of the oil is raised to 70° C. The oil is then separated and washed with hot water; this is attained by adding water to the oil and heating the mixture by means of a steam coil. The alcohol is evaporated, and the oil, after being separated from the water, is treated with fuller's earth at a temperature of 75° to 80° C. The alcohol used in the process may be recovered by distillation.—W. P. S.

Candles; Manufacture of stearine —. Comp. Luz Stearine. Fr. Pat. 394,362, Sept. 16, 1908.

CLAIM is made for the use of the insoluble fatty acids from the fat of the seeds of *Myristica bicuhyba* Humb. (ocuhuba fat).—C. A. M.

Emulsifying agents; Preparation of —. G. Imbert, Nürnberg, Bavaria. Eng. Pat. 11,121, May 22, 1908.

PATENTS.

Pigment; Manufacture of a white sulphate of lead —. J. B. Hannay, Cove Castle, Dumbartonshire, and S. B. Wilson, London. Eng. Pat. 6554, Mar. 24, 1908.

CLAIM is made for a continuous process in which the galena is introduced on to the top of the fuel in a furnace supplied with a hot-air blast, with the result that the solid and molten lead sulphide is protected from oxidation by means of its own vapours. The volatilised lead sulphide is carried upward in an atmosphere deprived of oxygen, and is oxidised to basic sulphate in a combustion chamber by the admission of an excess of cold air, followed by rapid cooling to prevent further changes. With suitable regulation there is a continuous formation of a product, the composition of which varies only within the limits of $\text{PbSO}_4 \cdot \text{PbO}$ and $2\text{PbSO}_4 \cdot \text{PbO}$; the yield of pigment is practically equal to the theoretical quantity. In special apparatus claimed for the process, the furnace is provided with rotating fire-bars cooled by means of water, so that the ash may be automatically removed from the bottom without interfering with the normal circulation of the gases.—C. A. M.

Rubber; Bitinga — from *Raphionacme utilis*. Bull. Imp. Inst., 1908, 6, 390—393.

THE plant, *Raphionacme utilis*, is known in Portuguese West Africa as "bitinga," "ecanda," and "marianga"; its tuberous roots contain a rubber-yielding latex. Specimens of the roots and of the rubber were examined. The tubers as received were covered with a dark brown scaly bark and contained about 87—89 per cent. of moisture; the yield of rubber from the dry substance was, on the average, 10.5 per cent. The specimen of rubber consisted of one piece of a pale yellowish-brown colour and two pieces of darker colour. The physical qualities of the rubber were fairly good. The light-coloured sample gave the following results on analysis: moisture, 1.0; caoutchouc, 76.8; resin, 9.0; protein, 0.6; insoluble matter (including ash, 7.11), 12.6 per cent. It was valued at 1s. to 1s. 3d. per lb., compared with fine hard Para rubber at 4s. 10d., but would probably be worth 3s. or more per lb. if properly prepared and freed from foreign matter.—A. S.

Ebonite; Analysis of —. G. Hübener. Chem.-Zeit., 1909, 33, 144—145, 155—157.

BROMINE water acts readily upon finely divided ebonite converting it into a friable bromine derivative, in which all the unsaturated linkages of the original (partially) sulphurised molecule are satisfied by bromine. By determining the combined bromine, the amount of caoutchouc hydrocarbon which is not fully sulphurised is ascertained, making use of the formula, $\text{C}_{10}\text{H}_{16}\text{Br}_4$, for the caoutchouc bromide. The remainder of the rubber hydrocarbon may be assumed to be present as disulphide, $\text{C}_{10}\text{H}_{16}\text{S}_2$, for the purposes of calculation, and may be estimated from the sulphur of vulcanisation. The latter is found by subtracting from the total sulphur, the free sulphur (estimated as described below) and the sulphur of the sulphates of certain metals present in the ash. The process is carried out as follows:—0.1 grm. of the finely divided ebonite is covered with about 75 c.c. of water and 10 c.c. of bromine, and kept at a moderate temperature until the action of the bromine is complete, and most of the excess is volatilised. The remaining bromine is then driven off by raising the temperature. The grey, flocculent solid is filtered off, and the free sulphur (which has now been oxidised to sulphuric acid) estimated in the filtrate by precipitation with barium chloride. The bromo-derivative is transferred to a flask, and heated with 10—15 c.c. of nitric acid (sp. gr. 1.4), free from halogen, in presence of 25 c.c. of $N/10$ silver nitrate, until fumes are given off. The liquid is evaporated to about 15 c.c. in bulk, diluted with water, and 5 c.c. of a saturated solution of iron alum added. The excess of silver is determined by titration with thiocyanate, and from the amount of silver converted into bromide, the amount of combined bromine is calculated. From this figure the amount of caoutchouc as bromide is ascertained as already explained. Total sulphur is determined in the usual way. When lead, calcium, or barium compounds are present in the ash, these must be estimated, and the amount of sulphur in the corresponding sulphates must be added to the free sulphur already estimated. For, either these metals are present as sulphates in the original vulcanised mixing, or are converted into sulphates by the action of the bromine or of the sulphuric acid formed by its action upon the free sulphur. The results displayed by the author are as follows:—In the case of a mixing in which, before vulcanisation, 29—31 per cent. of caoutchouc was found (by Buddle's method) the vulcanised product showed, in two experiments, free sulphur, 17.85 and 17.62

total sulphur, 22.00 and 22.00; caoutchouc (as bromide), 21.76 and 20.57; caoutchouc (as sulphide), 8.8 and 9.31; and total caoutchouc, 30.57 and 29.88 per cent. By slight modifications, the process may be made a gravimetric one throughout. Results obtained in this way, with the same sample, were: free sulphur, 18.12 and 17.75; total sulphur, 22.0 and 22.0; caoutchouc (as sulphide), 8.24 and 9.04; caoutchouc (as bromide), 21.35 and 22.42; and total caoutchouc, 29.59 and 31.46 per cent. By extraction with carbon bisulphide, the actual caoutchouc tetrabromide, $C_{10}H_{16}Br_4$, can be removed from the brominated vulcanised rubber, and the amount of this, in the sample under examination, corresponded with 13.2 per cent. of caoutchouc, calculated on the original substance. This proportion of the $C_{10}H_{16}$ molecules is therefore present in the vulcanised product without any combined sulphur. By estimating the bromine in the insoluble portion of the bromo-derivative, it was found that the whole of the remainder of the vulcanised rubber was present as $C_{10}H_{16}S$, no disulphide, $C_{10}H_{16}S_2$, being present.—E. W. L.

PATENTS.

Caoutchouc adhesive solution; Non-inflammable — H. Pichon and T. Truchelut. Fr. Pat. 394,477, Sept. 17, 1908.

A RESIN, such as copal or shellac, is added to a solution of caoutchouc in carbon tetrachloride, with the result that the injurious effect of the traces of sulphur chloride in the solvent on the adhesiveness is prevented. The resin is best added in the form of a solution in alcohol, petroleum spirit, or other solvent miscible with carbon tetrachloride. —C. A. M.

Jelutong ("dead-borneo," bask, pontianac); Process of rendering — capable of transport and storage. Hüttenbach und Co. Ger. Pat. 206,222, July 13, 1907.

THE jelutong is pressed in order to remove the greater part of the moisture it contains; it is then warmed, and whilst still moist, pressed into balls or the like, and finally coated with animal or vegetable glue which is subsequently rendered insoluble by treatment with formalin, bichromate, or other suitable agent.—A. S.

Elastic plastic mass from acetylene; Process for the preparation of an — L. Horwitz. Ger. Pat. 205,705, Jan. 22, 1907.

ELASTIC plastic masses are obtained by acting on metals or their oxides or salts with acetylene in presence of gases such as oxygen or air, or of substances capable of yielding oxygen. Special claim is made for the action of such mixtures of acetylene and oxygen, etc., on a mixture of copper and nickel. The products contain only very small proportions of the metal (e.g. less than 0.2 per cent.), which manifestly acts as a catalyst.—A. S.

Leather manufacture; Chemical and biological researches on — G. Abt. Bull. Soc. d'Encour., 1908, 110, 1449—1466.

A USEFUL summary of the present state of knowledge on the subjects named.—H. G. B.

Sole leather; American — C. A. Brown. J. Amer. Leather Chem. Assoc., 1909, 4, 38—52.

THE article deals with American sole-leather from the shoe manufacturer's point of view. The author divides sole leather into two classes, namely hemlock or red leather tannage, and oak and union tannage. The former was produced in much greater quantities than the latter, and was used for cheaper classes of boots, making a very stiff and unyielding shoe, but owing to its hard and coarse-fibred nature, it did not adapt itself readily to the Goodyear welt process. The oak and union leather was used for the finer grades, and almost exclusively in all women's shoes. The introduction of the Goodyear process of welting (some 25 years ago), and its universal adoption, restricted

the use of hemlock leather on account of its unyielding nature, and that of the union leather mainly on account of its high price. Attempts were made by the shoe manufacturer to soften the hemlock leather, but this was found to be neither practical nor economical, except in the hands of large manufacturers who required mellow sole leather in large quantities at popular prices. Oak and union leathers were now being put on the market at much lower prices, owing to the demand for them in other directions. The tanners in producing cheaper classes of sole-leather began to use both weighting and bleaching agents; this resulted in loss to the shoe-manufacturer as fewer soles to the pound of leather were cut than formerly, and these of indifferent wearing ability. At present the use of tanning extracts seems to have superseded to a large extent that of hemlock bark in the tannage of American sole leather.—H. BR.

PATENTS.

Glue-tester. E. S. Smith, Niagara Falls, N.Y. U.S. Pat. 911,277, Feb. 2, 1909.

THE apparatus consists of a pressure chamber, one side of which is provided with a flexible elastic membrane; this membrane is brought into contact with the surface of the gelatinous substance to be tested, and means are provided for generating pressure in the chamber, thereby expanding the membrane and displacing the gelatinous substance. Means are also supplied for measuring the amount of such displacement, and for measuring the pressure in the chamber.—W. P. S.

Plastic material [artificial horn, etc.]. W. Claypoole, Thornton Heath, Surrey. Eng. Pat. 2122, Jan. 30, 1908.

PHENOL, cresol, or the like (e.g. 1 litre of carbolic acid) are mixed with formaldehyde (e.g. 750 c.c. of 40 per cent. formalin), and caustic soda (e.g. 20 grms.), and the mixture heated until sufficiently viscous. It is then poured into moulds, etc., and kept at about 75° C. until set, after which it is removed, heated below 100° C. to expel water, and baked until of a horn-like consistency. The presence of the caustic soda acts as an accelerator in the first or condensation reaction, and prevents the separation of water, whilst it does not interfere with the second or polymerisation reaction in the baking process, but on the contrary, reduces the time required in the oven. Sodium carbonate, sodium cresylate, or similar compounds may take the place of caustic soda. If the accelerator is not added until the second reaction (i.e. during the baking), the product will be transparent. If desired, pigments may be incorporated with the material, or small proportions of glycerin, paraffin, gums, resins, etc., may be introduced. (Compare Fr. Pat. 353,995 of 1905, this J. 1905, 1081; 1906, 195.)—C. A. M.

XV.—MANURES, &c.

Calcium cyanamide. J. Aeby. Chem.-Zeit., 1909, 33, 145.

A CONSIGNMENT of calcium cyanamide lying on the quay pending shipment gave off an unpleasant smell, and was found on investigation by the author to contain 3.4 per cent. of calcium carbide, which, reacting with atmospheric moisture, was evolving acetylene. The author suggests that contracts for the supply of calcium cyanamide should specify a maximum amount of calcium carbide, not to be exceeded; not only because of the danger during transport of samples containing an appreciable proportion, but also because of the doubtless harmful effect of acetylene upon growing plants.—I. T. D.

Determination of phosphates. Estes. See XXIII.

PATENTS.

Superphosphates; Method of, and apparatus for, removing — from a decomposition chamber. G. Hövermann, Hamburg, Germany. Eng. Pat. 19,988, Sept. 23, 1908.

THE decomposition chamber is made conical at the bottom, and has a central rotary shaft, the cutting

device attached to the shaft being so arranged that the material is cut away in slices along a conical or vertical surface, so that the cut material can fall uniformly and regularly through a central discharging aperture on to a conveyor. The cutters may form an inverted cone, and the shaft to which they are attached may be made to sink gradually as they cut through the material; or else, a rotary hollow shaft, through which extends a fixed spindle, may pass through the bottom of the chamber, and a combined vertical and inclined cutter, pivoted together, be so geared to the spindle that it removes thin vertical slices of the material, from the centre outwards, as the hollow shaft rotates, the thickness of the slice diminishing as cutting proceeds, so that a constant quantity is cut away at each revolution. In the latter case the discharging aperture is closed during charging by a hollow core let down from above, and in the former case a core is lifted into the chamber from below. The present invention very much reduces the strain to which the material is subjected and also lessens the power required for moving it.—F. Sopn.

Fertilisers; Process of making complete — J. R. Young, Norfolk, Va. U.S. Pat. 911,283, Feb. 2, 1909.

A MIXTURE consisting of from 300 to 500 lb. of powdered calcium phosphate (bone phosphate), 600 lb. of vegetable matter containing potash, and from 400 to 700 lb. of "undried press-cake of nitrogenous organic matter" or "a suitable ammoniate" containing 40–50 per cent. of moisture, is treated with from 300 to 500 lb. of sulphuric acid of about 66° B. The mass is agitated until the action partially subsides, and is then allowed to set.

—W. P. S.

XVI.—SUGAR, STARCH, GUM, &c.

Sugar syrups; New method for the refractometric examination of impure — J. Tischtschenko. Z. Ver. deut. Zuckerind., 1909, 103–108.

THE refractometric determination of dry substance in lark, impure waste syrups is generally inaccurate owing to the high dispersion which renders the limit of total reflection ill-defined, and also, owing to the high proportion of non-sugar substances which have not the same refractive index as sucrose. To obtain a sharper reading, dilution of such syrups with water has been recommended; the Customs method elaborated by Herzfeld consists in diluting the syrup with water in the ratio 1 : 1 (compare Jappmann, this J., 1908, 698). The author points out, however, that this method is open to several objections. Thus, contraction occurs on dilution with water, the proportion of non-sugar to sugar remains unchanged, the limit of total reflection is still somewhat ill-defined, evaporation of water occurs, and the error of reading is increased since the scale divisions of the Abbé refractometer are smaller for low than for high refractive indices. The author therefore recommends that the sample should be diluted, not with water, but with a pure concentrated sugar solution of known sugar-content. A known weight of the sample is thoroughly mixed with a known weight (approximately equal quantities of each) of the sugar solution and examined by means of the Abbé refractometer at 20° C. The dry substance-content (x) of the original sample is obtained from the formula,

$$x = \frac{(a+b)P - bp}{a}$$

which a = weight of original sample, b = weight of sugar solution, p = percentage of sugar in the sugar solution (determined refractometrically), and P = percentage of dry substance in the mixture, determined refractometrically. If equal weights of sample and sugar solution be taken, the equation is simplified to $x = 2P - p$. The author has compared the results obtained refractometrically, using water and sugar solution (of 3 per cent. sugar-content) respectively for dilution, with the true content of dry substance found from determination of the water. It was found that by using sugar solution instead of water for dilution, considerably

greater accuracy was attained, the results seldom varying beyond permissible limits; these results had a tendency to be higher than the true value; this was largely owing to the fact that the sugar solution added was less concentrated than the molasses, contraction thus being not completely eliminated.—L. E.

Sugar in bagasse; Determination of — H. Pellet. Bull. Assoc. Chim. Sucri. et Dist., 1909, 26, 558–559.

THE ordinary process for determining sugar in bagasse does not give the total loss of sugar since the liquor expressed from the exhausted bagasse has a higher sugar-content than that which serves for calculating the loss of sugar. In spite of this well-known fact, however, it has been suggested that the differences observed between the results obtained by this process (or Java process as the author terms it) and those obtained by the Zamaron process (this J., 1898, 75) may be due to solution or formation of a dextrorotatory substance in the latter process. The author has found, however, that the liquid obtained by repeated extraction of bagasse from which all the sugar has been removed by Zamaron's process of successive extraction, is optically inactive, and considers that for the accurate determination of sugar in bagasse, successive extractions with boiling water by means of Zamaron's apparatus must be used.—L. E.

Maltose; Hydrolysis of — with citric acid. J. Pieraerts. Bull. Assoc. Chim. Sucri. et Dist., 1909, 26, 562–573.

THE author has made three series of experiments on the hydrolysis of maltose with citric acid. In each experiment of the first series, 50 c.c. of a 2.5 per cent. solution of hydrated maltose were heated to boiling with 10 c.c. of a 20 per cent. solution of citric acid under a reflux condenser. The periods of boiling were increased progressively throughout the series, and the degree of hydrolysis in each experiment was determined polarimetrically and by means of the cupric-reducing power of the solution. In the latter determinations, correction was made for the reducing action of the citric acid; special experiments showed that the reducing powers of maltose and dextrose in mixtures of these sugars are practically independent of each other. In the second and third series of experiments, the hydrolysis was carried out in an autoclave under pressures of 0.75 and 1.5 atmospheres respectively; otherwise, the conditions were the same as in the first series. The experiments showed that maltose is completely hydrolysed by boiling with citric acid as above described for about 30 hours, the solution becoming more or less yellow as a result of this treatment. The time required for hydrolysis is much decreased by heating under pressure; thus, under a pressure of 1.5 atmospheres, hydrolysis is complete in 2½ hours and before the solution has acquired a yellow colour.—L. E.

XVII.—BREWING, WINES, SPIRITS, &c.

Enzymes; Electrical migration of — L. Invertase. L. Michaelis. Biochem. Zeits., 1909, 16, 81–86.

THE author has carried out migration experiments on yeast invertase by means of the cell,

Zn | ZnSO₄ | Water | Invertase | Water | ZnSO₄ | Zn, which arrangement prevents the invertase from being subjected to the action of acids and bases formed as the result of secondary electrolytic reactions; indeed, with the arrangement employed, no acid or alkali can be detected in the second or fourth compartment, originally containing water, after a current of about 0.0005 ampère has been passing for 48 hours. At the end of the experiment, the solutions of the two water

compartments were tested for the presence of invertase by means of a solution of sucrose. The three separate experiments made, showed conclusively that the invertase moves towards the anode and must hence be regarded as possessing an acid character. This result confirms those yielded by the adsorption analysis of the invertase of yeast (see Michaelis and Ehrenreich, this J., 1908, 701.)

T. H. P.

Maize. The maltases of — R. Huere. Compt. rend., 1909, 148, 300—302.

THE author has studied the properties of the maltase secreted by two varieties of maize grown on the Landes: (1). *Early white maize*. The infusion of this grain contains an enzyme which converts maltose into dextrose very energetically at a temperature of 15° C. It is still slightly active at temperatures of 0° C. and even below. Its action is destroyed after 2 hours' heating at 50° C.; it has a slight action at 60° C., but is quite inactive at 65° C. The enzyme acts most rapidly at temperatures about 40° C. When the infusion is caused to act on starch paste, the action of the amylase at 50° C. is more rapid than that of the maltase; the latter is ultimately destroyed at that temperature, and the product contains both maltose and dextrose. At a temperature of 15° C. the action of the maltase keeps pace with that of the amylase, and dextrose is the only sugar produced. (2). *Early yellow maize*. The maltase of this grain is not active at temperatures below 20° C.; it is not entirely destroyed by heating at 80° C. The enzyme acts most rapidly at a temperature of 60°—62° C. Thus, no dextrose is produced by the saccharification of starch paste by an infusion of this grain at 20° C.; the result is the same as if amylase were the only enzyme present. The author terms the maltase of yellow maize a "high maltase," in contradistinction to that of the white maize; the latter maltase resembles the maltase of yeast in its temperature relationships.—J. F. B.

Digestion: Preliminary — of the mash. E. Moulang. Woch. f. Brau., 1909, 26, 77—81. (See also this J., 1909, 34, 154.)

THE author's experiments show that preliminary digestion of the malt grist with water does, under some circumstances, increase the yield of extract obtained. This increase is not merely an apparent one, as is shown by the diminution in the amount of the dry matter of the grains; it consists principally of starch, protein, ash, and pentosans. Malts with high content of enzymes usually exhibit the greatest increases of extract by this process. The increase of extract is influenced by: (1), the duration of digestion, the optimum being 8 hours at 15° C.; (2), the temperature during the first mashing, for which the optimum is 40—55° C.; (3), the physiological and physical condition of the malt. The quality of the beer prepared from a digested mash may, but need not, suffer; beer with bad colour and smell may, under some conditions, be obtained from badly-cured malts or malts made from coarse, thick-skinned barleys. The process of warm steeping promises to obviate such difficulties.—T. H. P.

Digestion of malt. F. Emslander. Z. ges. Brauw., 1909, 32, 77—78. (See also this J., 1909, 34, 154.)

THE author's experience, extending over many years, shows that standing of the cold mash overnight or, in the winter for 24 hours, is accompanied by increase of the extract and of the amount of fermentation. It has been stated that this procedure, especially in the summer, leads to the ready formation of lactic acid. The author has however frequently observed that the formation of lactic acid is diminished by increasing the period of stand of the cold mash and by stirring of the mash. He cools the mashing liquor in the summer to 8° R. (50° F.) by means of ice and also mixes in ice with the mash, so as to prevent heating due to the swelling of the malt. The results obtained in the brewery are confirmed by those of laboratory experiments.

Beers from pre-mashed malts. W. Windisch. Woch. f. Brau., 1909, 26, 67—70.

THE author elects in future to describe as "pre-mashed" (*vermisch*), those beers produced by processes in which the malt is allowed to stand wet for some time before the mashing is proceeded with. A series of eight experiments is recorded in which malt from the same bulk was mashed in various ways, and the resulting beers compared. The malt was not very well grown and only moderately modified. In one instance the malt was mashed by the ordinary decoction method and in the others, various times of "stand" at ordinary or higher temperature were allowed before a saccharifying heat was attained. For details the original must be consulted. In all cases an increase of yield over the simple decoction brew was obtained. The fermentations were normal and the differences of flavour so slight that none but an expert could detect them. The colour in a few cases was slightly reddened. The beer obtained in the experiment where a three hour stand at 120° F. was allowed before mashing, which gave the highest yield of extract, was the least satisfactory. The bulk of the increase in extract obtained is not produced from extra conversion of starch. (See also this J., 1909, 34, 154.)—R. L. S.

Spirits: Comparative analyses of — distilled in air and under vacuum. Girard and Chauvin. Monit. scient., 1909, 23, 73—89.

THE authors have carried out an investigation at the Paris Municipal Laboratory on the use of a vacuum distillation apparatus in the analysis of potable spirits. The apparatus is shown in the figure, and is so designed as to avoid direct communication between the vacuum pump and the liquid under distillation. B (see fig.) is the distillation flask, holding 300 c.c. of the spirit to be distilled; the funnel, V, is partially filled with water for rinsing out after distillation. The condensing worm, S, is immersed in a vessel of running water at a temperature which must not be allowed to exceed 15° C. The first receiver, F', is surrounded by a freezing mixture of ice and salt, as is also the second, safety-receiver, F''; R² is a cock for breaking the vacuum. The 3-litre bottle, F, acts as a vacuum reservoir and communicates with the pump by the cock, R. When the distillation flask is charged, the cock, R³, is closed and the vessels, F, F', and B, are exhausted. The pump is then cut off by closing R, and the cock, R³, is opened, so that the flask, B, is nearly exhausted. R³ is then closed and a full vacuum created in F, which is used for maintaining the vacuum in the distillation flask as it falls during distillation, B being closed and R' opened when necessary. Distillation should begin at 20—22° C. and should be one-third completed by the time a temperature of 25° C. is reached towards the end it is necessary to raise the temperature very cautiously, finishing off at 38° C. If the operation be properly conducted, the second receiver, F'', should contain not more than 2—3 c.c. of liquid, which must be mixed with the distillate in B'; the bottle, F, should not contain any of the distillate. Comparative analyses of the distillates, obtained in this way, and of those obtained by ordinary distillation in air, showed that the fusural and the higher alcohols were identical in both methods. The alcoholic strengths were also identical. The aldehyde were always greater in quantity after ordinary distillation than with vacuum distillation. The esters showed low

results in the case of cognac and mare brandies, and higher results in the case of rums and cherry brandies, after vacuum distillation, as compared with ordinary distillation. The sum of the acidities (volatile and non-volatile) after vacuum distillation was practically identical with the total acidity of the original spirit, whereas with ordinary distillation the total acidity is always increased. A series of six distillations *in vacuo* made at different times with the same sample of spirit gave concordant results. The vacuum method of distillation gives a distillate of which the composition depends less on the skill of the chemist than the ordinary method, and since the mode of heating and condensation is strictly regular, and the chemical action of the air is excluded, the results must be considered to be more accurate than with the ordinary method of distillation. The authors also show that, in ordinary distillation, the analytical results are considerably affected by the manner in which the distillate is collected.—J. F. B.

"Cognac" obtained from *cactus figs* [prickly pears]. A. Sanna. Staz. sperim. agrar. ital., 1908, 41, 550—561. Chem. Zentr., 1909, 1, 675.

THE author drew attention first in 1900 (Annuario della R. Scuola Enologica di Cagliari, 5, 67) to the suitability of *cactus figs* (*Opuntia tuna*, Mill.) for the manufacture of alcohol. Each fruit weighs on the average 104 grms.; it contains 37 per cent. of husk, 4.2 of seeds, 6.75 of proteins, 1.34 of cellulose, and 0.28 of fat. The husks contain 65.84 per cent. of water, 2.81 of ash, and 31.35 of organic matter; the shelled fruit contains 63.32 per cent. of water, 0.9 of ash, and 35.76 of organic matter. The juice contains 15.54 per cent. of extractive substances, 0.1 of free acid, 0.69 of ash, and 11.2 of sugar. For the preparation of spirit, the crushed fruit is pressed in linen bags, and the red juice is mixed with 2 per cent. of vigorously fermenting must, and 2 per 1000 of tartaric acid. When vigorous fermentation is finished, the liquor is distilled on the water-bath. From 196 kilos. of figs, 122 litres of distillate are obtained, equivalent to 16 litres of 45 per cent. alcohol. This distillate is rectified so as to obtain a spirit containing 58 per cent. of alcohol, and this when stored in casks for four years under suitable conditions, yields a cognac, which, it is stated, corresponds completely with genuine cognac.—A. S.

Rum; *Distinction between Jamaica and artificial* —. K. Micko. Z. Untersuch. Nahr. Genussm., 1908, 16, 433.

THE aroma of genuine Jamaica rum is due to a constituent which is neither present in European spirits nor in artificial products. This constituent is a colourless substance, liquid and non-volatile at the ordinary temperature, it boils at a higher temperature than alcohol, is insoluble in dilute caustic soda, and has the general characters of an essential oil; it is not an ester, aldehyde, or ketone. For the distinction of genuine Jamaica rum from artificial products, the odour and taste offer the best means, aided by a process of fractional distillation, the characteristic aroma of the natural product being less volatile than that of the fictitious article. 200 c.c. of the spirit are diluted with 30 c.c. of water, and distilled, seven fractions, each of 25 c.c., being collected. The first two or three fractions contain the esters of formic and acetic acid, and alcohol. The odour of artificial rum comes over mainly in the following fraction. That of genuine Jamaica rum does not generally appear until the fifth and sixth fractions.—J. O. B.

PATENTS.

Falt liquors; Priming of —. W. J. Melhuish. Glasgow. Eng. Pat. 13,528, June 25, 1908.

THE use of lactose is claimed for the priming of malt liquors.—J. F. B.

Ferment and process of producing it. A. D. Barr, Assignor to Mead Johnson and Co., Jersey City, N.J. U.S. Pat. 911,803, Feb. 9, 1909.

FERMENT is prepared by mixing pancreatin, yeast, sugar, and water, allowing the mixture to stand, evapor-

ating, placing the product in a suitable alkaline culture-medium, allowing it to stand, and evaporating. Generally stated, the constituents are: a proteolytic ferment, an organised ferment, carbohydrate matter, and water.

—J. F. B.

Australian tree called "blackboy"; Industrial utilisation of the — [production of alcohol, sugar, gums, and resins]. R. W. Wallace and G. Reynaud. Tr. Pat. 394,234, Nov. 20, 1907.

THE tree known in Australia under the name of "black-boy" consists of an inner, woody portion rich in saccharine matter, whilst the bark contains considerable quantities of gums, "guttas," and resins. The sugar is analogous to maple sugar, and the woody portion also contains yeasts or ferments. The process described consists in separating the woody portion from the bark, macerating the former with water, and allowing fermentation to take place; the dilute alcoholic solution obtained may then be employed for extracting a further quantity of the wood, until the alcoholic strength of the solution is such that it is worth while to distil the alcohol. The gums, etc., are obtained by treating the finely divided bark with a suitable solvent such, for instance, as the alcohol produced in the first part of the process. Or, the bark may be subjected to the action of the alcoholic vapours produced in the distillation, before these vapours are condensed. The solution containing the gums and resins is then evaporated so that the alcohol may be recovered. The residue obtained from the evaporation is utilisable as such, or the gums may be separated from the resins, etc. by a process of sifting.

—W. P. S.

Worts; After-saccharification of dextrinous —. R. Dietsche. Ger. Pat. 205,057, May 20, 1908. Addition to Ger. Pat. 181,581.

ACCORDING to the main patent (181,581), the wort was run off as hot as possible and was then boiled with the hops, and after a certain time, the boiling was interrupted, the wort cooled to about 70° C., cold mash added, and when the after-saccharification was complete, the whole again boiled, or at least heated to 80°—90° C., to destroy the diastase. According to the present additional patent, the mashing is performed with only the husks and grits of the malt, the hot wort is run off and boiled with the hops and then cooled to about 70° C. The malt flour is added to the cooled wort along with the cold mash and is rapidly saccharified. The wort is then again boiled in order to destroy the diastase.—A. S.

XVIII.—FOODS; SANITATION; WATER PURIFICATION, AND DISINFECTANTS.

(A.)—FOODS.

Cocoa; New method of determining theobromine in —. A. Kreutz. Z. Untersuch. Nahr. Genussm., 1908, 16, 579—584.

THE free theobromine is determined as described in this J., 1909, 215. For the determination of the combined theobromine, the cocoa residue on the filter is dried, transferred to the original flask, and heated with 4 per cent. sulphuric acid for about 45 minutes, under a reflux condenser. The hot liquid is transferred to a beaker, neutralised with barium carbonate, and evaporated to dryness in a Hoffmeister capsule. The capsule and contents are then disintegrated with pure sand, and the powder extracted with chloroform for 5 hours in a Soxhlet apparatus. After distilling off the solvent, the white residue is weighed; it represents the theobromine present in the cocoa in the combined form.

—J. O. B.

Formaldehyde; Effect of — upon digestion and health. H. W. Wiley. United States Dept. of Agricult., Bureau of Chem., Circular No. 42, Dec. 21, 1908.

"FORMALDEHYDE is one of those preservatives the use of which in foods has been almost universally condemned by experts, physicians, and the general public." Neverthe-

less, as formaldehyde has heretofore been considerably used in certain foods, especially in dairy products, and is still advertised under its own and other names for use in such products to a limited extent, the author deemed it wise to investigate the question. Medical data indicate plainly that formaldehyde, even taken in small quantities, acts as an irritant to the mucous membrane, the normal organs being at once actively stimulated so as to create for the time a false appetite. The final conclusion arrived at is that the addition of formaldehyde to foods tends to derange metabolism, disturb the normal functions, and produce irritation and undue stimulation of the secretory activities, and is therefore never justifiable.

African oils and oil seeds. See XII.

PATENTS.

Milk: Dedicating — J. H. Campbell, New York, and C. H. Campbell, Philadelphia, Assignors to National Nutrient Co., Jersey City, N.J. U.S. Pat. 910,784, January 26, 1909.

PARTIALLY skimmed milk is heated to a temperature below the coagulating point of albumin, and subjected to a blast of air until it is concentrated to a thick liquid. The latter is then delivered, in the form of a thin layer, on to the surface of a revolving drum heated internally to a temperature below 158° F. The dry film is removed from the surface of the drum before the latter has made a complete revolution, and the practically solid material thus obtained is further dried, and powdered.—W. P. S.

Proteids [casein] from buttermilk; Process of producing certain — L. H. Reuter, Berkeley, Cal. U.S. Pat. 911,269, Feb. 2, 1909.

THE buttermilk is treated, at a temperature of about 32° F., with alkali in order to neutralize the acidity and convert the casein into a soluble compound: the mixture is then heated to about 150° F. for 1 hour or more, with constant stirring, and next boiled for about 1 minute, so as to separate completely the albumin from the soluble casein. After cooling and clarifying, the mixture is filtered and the casein is precipitated from the heated filtrate by means of sulphurous acid.—W. P. S.

Potatoes; Process of treating the juice of — R. Goldschmidt, Taikowitz, Austria. Eng. Pat. 8699, April 21, 1908.

SEE Fr. Pat. 390,018 of 1908; this J., 1908, 1077.—T. F. B.

(B.)—SANITATION; WATER PURIFICATION.

Drinking water; Purification of — Times Eng. Suppl., Feb. 17, 1909.

ATTENTION is now being directed to non-submerged sand-filters for the purification of potable waters, and Dr. Miquel (of the Saint-Maur Experim. Station, Paris.) has lately conducted a long series of interesting experiments. The principle of the sand-filter, not submerged or sunk below the water-line, is as follows:—On a bed of fine-grained sand, 1·20 metre in thickness, the water undergoing purification is distributed in the form of fine rain. The surface of the filter must never become covered with a layer of liquid, even of the thinnest character. The water penetrates into the sand, percolates through it, and issues freed from any bacteria it may have previously contained. The filter must be thoroughly drained at its base. The sand must be of a fairly fine grain, preferably such as will pass through a sieve with meshes of 1 square mm. in size. Dr. Miquel's tests have been carried out with experimental filters constructed of sheet iron, 80 cm. in diameter. He has ascertained that thicknesses of sand less than 1·20 metre in depth were insufficient to effect the sterilisation of the water. The sterilisation is defective for a time after starting a new filter, but at the end of a few days, or in some cases after several weeks, it becomes satisfactory. It then wholly removes all the bacteria, and may continue

to work properly for many months without cleansing. In those instances where the liquid under treatment is the turbid water of a river, the degeneration of the filter is more rapid, but this can be avoided by a preliminary straining process in a non-submerged filter only 30 cm. in depth. The town of Chateaudun, where for many years past typhoid fever has been prevalent, has just proceeded to instal a filter on this principle, and the results obtained there have recently been laid before the Society of Civil Engineers. Sand from the river Loire was used, screened through a millimetre sieve. The filter-bed has a superficial area of 250 square metres, and the speed of filtration ranges between three and five cubic metres per metre of surface in 24 hours. It has been shown by an analysis that all the injurious bacteria were removed, and it has also been demonstrated that it is essential to avoid clogging the filter.

PATENTS.

Sewage; Treatment of — E. W. Ives, Gomersal, Yorks. Eng. Pat. 10,557, May 15, 1908.

THE invention relates to the construction of a tank or filter in which the sewage is treated. Inclined walls or slabs are placed across a tank, the walls reaching nearly to the bottom and top alternately, so that the sewage is caused to pass successively under one wall and over the next. The space between the walls may be filled with any suitable filtering material.—W. P. S.

Sewage and the like; Apparatus for the purification of — by means of sieves placed in the current of liquid. G. Windschild. Fr. Pat. 394,582, Sept. 23, 1908. Under Int. Conv., Feb. 17, and July 29, 1908.

THE sieves have the form of conical drums which are mounted horizontally, so that the lower side of the drum is immersed in the sewage or water flowing along a channel. The drums are rotated and the matters collecting on the sieves are removed by jets of compressed air when the sieve reaches the uppermost position. The jets of air are admitted to the outside of the sieve through pipes having slit-like openings, and the solid matters fall from the sieves into a shoot by which they are carried away. Means are provided for causing the pipes supplying the air-jets to pass to and fro over the surface of the sieve, and partitions or ribs are fitted on the sieves so that the solid matters do not fall off before they are over the mouth of the shoot. The lower part of the drum is supported by rollers, and a second sieve may be fixed inside the main sieve.—W. P. S.

Water; Purification of — [electrolytically]. D. L. V. Browne, Assignor to J. B. Miller, San Francisco, Cal. U.S. Pat. 910,495, Jan. 26, 1909.

THE electrolytic vessel consists of a tank provided with an inlet and outlet, and furnished with a series of anodes and cathodes "made of iron, zinc, manganese dioxide, and aluminium, the various metals being alternately placed." A series of carbon anodes and cathodes is placed at the discharge end of the tank, in order to accelerate the "flocculation" of the hydrous oxides of the undesirable metals.—B. N.

(C.)—DISINFECTANTS.

Cresol soaps; Evaluation of solutions of — W. Spalteholz. Chem.-Zeit., 1909, 33, 181—182.

A METHOD of determining the amount of water in cresol soap is based upon the fact that such soaps give clear solutions with glacial acetic acid, and that these become turbid from the separation of cresols and fatty acids on the addition of a sufficient quantity of water. Cresol soaps containing about 61 per cent. of cresol, and water up to about 13 per cent. yield clear solutions with glacial acetic acid in all proportions. When the proportion of water is above 13 per cent., there is either an immediate turbidity, or there is solution followed by turbidity. On now adding more acetic acid, a clear solution is again obtained, after the addition of a certain amount. Thus when 5 c.c. of cresol soap are treated drop by drop with

glacial acetic acid and no turbidity results, the amount of water cannot exceed 13 per cent. On titrating 5 c.c. of a cresol soap with 50 per cent. acetic acid, the amount required to produce a permanent turbidity decreases with the increase in the proportion of water. This is shown in the following results obtained with a typical cresol soap on addition of 50 per cent. acetic acid:—

Per cent. of cresol in soap	66.7	64.0
Per cent. of water in soap	5.4	9.3
Acid required to produce first turbidity, in c.c.	—	0.4
" " " " clear solution	—	2.8
" " " " final turbidity	13.4	12.5

3—6 hours. In order to facilitate the resolution of the fibre bundles, petroleum is added to the material in the digester to the extent of 5—10 per cent. of the weight of the bagasse. The boiled material is then reduced to pulp and washed in a kneading machine, refined between horizontal millstones, strained, again refined in a Jordan mill and converted into paper. (2). A cellulose pulp is prepared by digestion with

62.7	60.7	53.9	50.6	48.9	47.2	45.5
11.2	14.0	23.6	28.4	30.8	33.1	35.4
0.2	0.1	turbid	turbid	turbid	turbid	turbid
3.1	3.5	4.3	4	5.0	5.4	—
12.0	11.8	9.7	8	8.0	6.9	—

In practice this affords a rapid means of determining, e.g., whether a delivery of soap is up to sample, and an increase of 1 per cent. of water may be readily detected by the use of acetic acid of definite strength as a reagent.

—C. A. M.

Ferrous arsenate as an insecticide on plants. Vermorel and Dantony. *Compt. rend.*, 1909, 148, 302—304.

ALL the soluble salts of arsenic have an injurious action on the green organs of plants, which prevents their use as insecticides. The insoluble cupric-arsenic compounds, Scheele's green and Schweinfurth's green, when mixed with lime, are efficient and innocuous insecticides, but they lack the quality of adhesion. Lead arsenate, prepared by double decomposition, possesses all the qualities required of a good insecticide, but its white colour may cause fatal mistakes, and its use has been forbidden in consequence. The authors have employed ferrous arsenate with success for three years, and contend that this compound is free from all objections. They prepare solutions containing 400 grms. of crystallised sodium arsenate and 60 grms. of ferrous sulphate per 10 litres respectively. The iron solution is added cautiously to the arsenate solution until the mixture shows a blue reaction with uricamide test paper; the mixture is then diluted to 100 litres for use. It is important that the iron salt should be a slight excess over the arsenate. The precipitate contains ferrous hydroxide in addition to ferrous arsenate; it has a dull green colour, is an efficient insecticide, and adheres well. The proportions indicated above produce a wash containing 200 grms. of ferrous arsenate per 100 litres; stronger washes, containing 500 grms. per 100 litres, adhere still more completely. Vines, which are the plants most sensitive to the "scorching" action of arsenic preparations, suffer no ill effects from the latter dose, but a wash of 200 grms. per 100 litres is quite sufficient.

—J. F. B.

XIX.—PAPER, PASTEBOARD, &c.

PATENTS.

Agar-cane and similar substances; Process of treating — G. D. Burton, Boston, Mass. U.S. Pat. 909,987, Jan. 19, 1909.

THE specification describes a variety of treatments of vegetable fibres, with baths of soap, of salts including alates, and of electrolytic products.—A. S.

From plants, esparto, etc.; Manufacture of cellulose from — by electro-chemical treatment. F. E. M. Dubrot and J. M. E. Lockhart. Fr. Pat. 394,111, Sept. 5, 1908.

PARTS and other plants, after steeping, are subjected to the action of an electric current in presence of a solution containing sodium chloride and "soda." In this way the cellulose fibres are separated from the parenchyma, and encrusting substances are dissolved.—J. F. B.

gasse; Treatment of — for conversion into cellulose or pulp for paper or boards. Comp. Industriel de Cellulose. Fr. Pat. 394,143, Aug. 8, 1908.

TWO kinds of pulp may be made:—(1). The bagasse is led with water under a pressure of 4—6 atmospheres for

alkaline solutions and treatment in a breaking engine and beater in the usual manner.—J. F. B.

Paper pulp [from seaweed]; Process for the manufacture of — V. J. Kuess. Fr. Pat. 394,494, Sept. 21, 1908.

PLANTS of the algæ group, particularly seaweeds of all varieties, are dried in the air, cleaned and freed from sand. They are then digested at a temperature between 125° and 130° C. with an alkaline solution, preferably composed of 2 kilos. of potassium carbonate, 1 kilo. of sodium carbonate, and 0.5 kilo. of sodium hydroxide per 100 litres. The digestion is complete after 1—2 hours, and the fibres are then treated mechanically in the usual manner.

—J. F. B.

Viscose; Manufacture of cellulose derivatives from — L. Lilienfeld, Vienna. Eng. Pat. 8798, April 21, 1908.

CELLULOSE derivatives which are stable in the dry condition and are soluble in dilute alkalis, ammonia, or even in warm water, are prepared by treating crude or purified viscose, or one of its derivatives, with an oxidising agent, such as a permanganate or manganate, and precipitating the product. For instance, 10 kilos. of a solution of the zinc salt of viscose in soda lye of 3—15 per cent. strength, containing 300—600 grms. of cellulose, are mixed with successive portions of a solution containing 50—180 grms. of potassium permanganate in 2—3 litres of water. The mixture thickens at first, but on continued agitation it becomes mobile. After standing for some hours, the manganese oxides are filtered off and the cellulose compound is precipitated by an acid; or else, the whole mixture is precipitated by acid and the manganese oxides are removed by sulphurous acid. The precipitated compound is finally washed and dried; it is then soluble in a 2 per cent. sodium hydroxide solution. The solution of the sodium or ammonium compound may be dried, so as to give a product soluble in water, or insoluble metallic compounds may be obtained by precipitation with a zinc or copper salt.—J. F. B.

Cellulose compositions; Manufacture of stable — E. A. L. Rouxeville. Fr. Pat. 393,310, June 1, 1908. Under Int. Conv., June 3, 1907.

THE modified terpene hydrocarbons described in previous patents (this J., 1906, 83; 1907, 988, 1133) are soluble in the same media and mix very intimately with nitro-cellulose, natural or vulcanised gums (caoutchouc, gutta-percha, shellac) and rubber substitutes; and compositions, which are considerably more stable than celluloid when heated, are made by mixing these substances, in various proportions according to the properties desired. In certain cases ordinary cellulose may be incorporated with the terpene product, and the mixture treated with nitric acid.—J. F. B.

Plastic masses, coatings, films, imitation leather, etc. [from cellulose]; Process of manufacturing — F. Meyer. Fr. Pat. 393,963, Aug. 29, 1908.

SOLUTIONS of cellulose compounds (nitrates, acetates, and viscose) are converted into the plastic condition by the simultaneous presence of both a solvent and a coagulating substance, in such proportions that the cellulose derivative is neither truly dissolved nor fully coagulated. These plastic compositions are not sticky and can be worked in a highly concentrated condition by the usual

spreading machines. If, for instance, cellulose acetate be employed, the plastic mass is made by means of a mixture of acetone and water. Such a mass can be applied to cloth or paper and at the same time a pattern may be impressed on it with an engraved roller.—J. F. B.

Cellulose threads, etc. Fr. Pat. 394,586. See V.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENTIAL OILS, AND EXTRACTS.

Enzymes capable of hydrolysing salicin and arbutin. W. Sigmund. Monatsb. Chem., 1909, 30, 77–87.

A NEW enzyme *salicase*, has been obtained from the twigs, bark and leaves of numerous varieties of willow and poplar. It slowly hydrolyses salicin to dextrose and saligenin, but is quite without action on amygdalin and is therefore not identical with emulsin. The enzyme is active either in the aqueous liquid obtained by soaking the twigs, etc., of the plant for 1–2 days or when precipitated from this by means of alcohol. In a similar manner an enzyme, *arbutase*, has been detected in ling (*Calluna vulgaris*) and bilberry (*Vaccinium myrtillus*), which hydrolyses arbutin to dextrose and quinol. This also is without action on amygdalin.—E. F. A.

Bark of Prunus serotina; Constituents of the —. Isolation of *l*-mandelonitrile glucoside. F. B. Power and C. W. Moore. Chem. Soc. Proc., 1909, 25, 27.

THE material employed, consisting of the air-dried bark of *Prunus serotina*, Ehrhart, yielded on maceration with water an amount of hydrogen cyanide corresponding with about 0.075 per cent. of its weight. It has been shown to contain *l*-mandelonitrile glucoside, $C_{11}H_{17}O_6N$ (m.p. 145–147° C.; $[\alpha]_D^{20} = -29.6$), which has also been obtained as its tetra-acetyl derivative (m.p. 136–137° C.; $[\alpha]_D^{20} = -24.0$), and an enzyme which hydrolyses β -glucosides. An alcoholic extract of the bark, on distillation with steam, yielded small amounts of benzoic acid and an essential oil, but no hydrogen cyanide. The non-volatile constituents of the bark consisted of a green resin, insoluble in either hot or cold water; a brown resin, soluble in the hot aqueous liquid, but deposited on cooling, and material which remained dissolved in the cold aqueous liquid. The green resin, amounting to about one per cent. of the weight of the bark, yielded a phytosterol, $C_{27}H_{46}O$ (m.p. 135–136° C.; $[\alpha]_D^{20} = -34.0$), palmitic, stearic, oleic, linolic, and isolinolenic acids, a little ipuranol, $C_{23}H_{38}O_2(OH)_2$, and, after acid hydrolysis, oleic acid, dextrose, and β -methylasculetin, $C_{10}H_8O_4$. The brown resin, amounting to about one per cent. of the weight of the bark, yielded, after acid hydrolysis, traces of a phytosterol, small amounts of oleic acid, β -methylasculetin, and dextrose, along with insoluble, red, resinous material. The portion of the alcoholic extract which was soluble in cold water contained the *l*-mandelonitrile glucoside, together with a quantity of sugar and tannin. It yielded, furthermore, benzoic, trimethylgallic, and *p*-cumaric acids, and traces of a substance melting at 240–241° C., and, after heating with dilute sulphuric acid, *l*-mandelic acid and β -methylasculetin were obtained.

Pinene; Oxidation of — with mercuric acetate. G. G. Henderson and J. W. Agnew. Chem. Soc. Proc., 1909, 25, 35.

By the action of aqueous mercuric acetate at the ordinary temperature, pinene is converted into sobrerol, $C_{10}H_{16}(OH)_2$, a compound formerly prepared by oxidising pinene with moist oxygen in sunlight, and sobrerol is oxidised to a hydroxyketone, $C_{10}H_{15}(OH)O$, when heated with the same reagent. The hydroxyketone is reduced to sobrerol when dissolved in moist ether and treated with sodium, and it yields carvacrol on reduction with aqueous hydriodic acid in the cold. When heated for a short time with anhydrous oxalic acid, it yields carvone together with some carvacrol, and when it is oxidised with an acidified solution of potassium permanganate, terpenylic acid is obtained. Hence it is concluded that the hydroxyketone is 8-hydroxy-carvotanacetone. Sobrerol can also be prepared by the

action of mercuric oxide on a cold solution of pinene in acetic acid, whilst if the solution be heated, the oxidation product is the hydroxyketone.

Essential oils; Constituents of —. Inversion of carvenene, $C_{10}H_{16}$, to isocarvenene. F. W. Semmler. Ber., 1909, 42, 522–527.

WHEN carvenene (this J., 1909, 106) is boiled with a 25 per cent. solution of sulphuric acid in alcohol, a terpene is produced. This is styled *isocarvenene*, and boils at 59–62° C. at 10 mm., has $n_D^{20} = 1.480$, and the sp. gr. 0.845 at 20° C. The terpinene obtained from sabinene dihydrochloride by the action of aniline was treated with bromine, when terpinolene tetrabromide was isolated. Carvenene, when reduced with sodium and amyl alcohol, forms dihydrocarvenene ($C_{10}H_{18}$, Δ^2 -tetrahydrocymene), which boils at 55–56° C. at 12 mm., and has the sp. gr. 0.824 at 20° C., and $n_D^{20} = 1.461$. By the oxidation of carvenene with ozone, a diketone, $C_8H_{14}O_2$, is produced, boiling at 82–86° C. at 10 mm., and having the sp. gr. 0.95 at 20° C., and $n_D^{20} = 1.433$; the dioxime melts at 130° C.—F. SHOX.

Cinnamomum zeylanicum, Breyer; Essential oil of the root-bark of —. A. A. L. Pilgrim. Pharm. Weekblad, 1909, 46, 50–54. Chem. Zentr., 1909, 1, 534.

THE light yellow oil has a strong odour of camphor; it is miscible with alcohol, ether, petroleum spirit, and benzene; and camphor, which is the chief constituent, separates from it even at the ordinary temperature. It contains also pinene, cineol, dipentene, phellandrene, eugenol, safrol, caryophyllene, and borneol. It has the sp. gr. 0.99366 at 15° C., and optical rotation, $+50.2^\circ$ in a 20 mm. tube.—A. S.

Suprarenine; A new synthesis of —. Note on K. Böttcher's communication. H. Pauly. Ber., 1909, 42, 484–485. (See this J., 1909, 218.)

THE author calls attention to the fact that Böttcher gives no analytical data or physical constants in support of his claim to have synthesised suprarenine (*loc. cit.*). Böttcher merely gives qualitative tests and asserts that his product has the same pharmacological action as suprarenine. The author recently attempted, without success, to produce suprarenine by the action of methylamine on 3:4-dihydroxyphenylhalogenethanolamine (Ber., 1908, 41, 4151), a method very similar to that adopted by Böttcher.—F. SHOX.

Atoxyl. III. F. Blumenthal and E. Jacoby. Biochem. Zeits., 1909, 16, 20–36. (See this J., 1908, 710.)

THE toxicity of atoxyl (sodium *p*-aminophenylarsinate) is affected by alteration of the amino-group in the sense indicated by Ehrlich and Berthelm (Ber., 1908, 40, 3292). Thus, introduction of an acetyl radical into the amino-group is accompanied by considerable diminution of the toxicity, which, however, is not affected by replacement of the amino-hydrogen by other groups, such as methyl. Complete replacement of the amino-group by iodine or hydroxyl results in increased toxicity. In the case of the mercury salt of *p*-aminophenylarsinic acid, changes in the amino-group have little influence on the toxicity. A non-poisonous product, such as the mercury salt of *p*-iodophenylarsinic acid, may, indeed, result, but the toxicity of the mercury compounds seems to be influenced more by the content of mercury than by any alteration of the amino-group. Changes in the arsenic group lead to very considerable variation in the poisonous properties, the reduction products of atoxyl and acetylatoxyl (arsacetin) being, under some circumstances, 20 to 30 times as toxic as atoxyl itself.—T. H. P.

Diphenylmethane; Preparation of —. A. Nastjukow. J. Russ. Phys.-Chem. Ges., 1908, 40, 1376–1379. Chem. Zentr., 1909, 1, 534–535.

THE author has improved the older method of preparing diphenylmethane and its homologues, by dispensing with the use of glacial acetic acid, and instead heating the mixture for 3 hours. In this way 25 grms. of diphenylmethane were obtained from 100 c.c. of formalin, 100 c.c.

of concentrated sulphuric acid, and 200 c.c. of benzene. Ditolylmethane and 3-3'-dinitrodiphenylmethane were prepared in a similar manner from toluene and nitrobenzene respectively.—A. S.

Nitromethane; Preparation of — W. Steinkopf, Ber., 1908, 41, 4457—4458.

The author describes an improvement of Preibisch's method (J. prakt. Chem., 1874, [2], 8, 310), whereby it is possible to obtain a yield of 49 per cent. of the theoretical quantity of nitromethane. A solution of 146 grms. of potassium carbonate in 200 grms. of water is added to a solution of 200 grms. of monochloroacetic acid in 200 grms. of water, the mixture being cooled. The precipitate formed redissolves on vigorous agitation. A solution of 300 grms. of potassium nitrite in 300 grms. of water is now added, and the whole is heated under a reflux condenser, until evolution of carbon dioxide begins, whereupon the flame is removed. The heat of the reaction is sufficient to keep the mixture boiling for some time, and the nitromethane distils over with the steam; the distillation is completed with the aid of the flame. The nitromethane is separated from the distillate, and the aqueous portion is redistilled three or four times to recover a further quantity. After drying with calcium chloride, the nitromethane is mixed with a quantity of mercuric oxide and again distilled.—A. S.

Nitromethane; Preparation of — A. Wahl, Bull. Soc. Chim., 1909, 5, 180—182.

The author has obtained yields of nitromethane amounting to from 50 to 52 per cent. of the theoretical quantity by a process somewhat different from that of Steinkopf (see preceding abstract). He uses throughout sodium salts instead of the corresponding potassium compounds; adds only one-fifth more than the theoretical quantity of nitrite; and distils over the nitromethane from the reaction product by means of a current of steam.—A. S.

Radioactive parent substances; Chemistry of the — D. Strömholm and T. Svedberg, Z. anorg. Chem., 1909, 61, 338—346.

The authors have applied the method of isomorphous crystallisation or precipitation to the study of radioactive substances, in the present paper to the study of thorium. It was found that Rutherford's thorium X is isomorphous with barium and lead and accompanies the former metal in precipitation-reactions; it must therefore belong to the group of alkaline-earth metals. Thorium 3 (radiothorium) is isomorphous with thorium and hence is probably quadrivalent. Thorium 2 is probably trivalent, being isomorphous with lanthanum.—A. S.

Radioactive product of the uranium series; A new — J. Darne, Compt. rend., 1909, 148, 337—339.

In treating the crude oxide of uranium X, obtained in the usual manner, with a small quantity of very dilute hydrochloric acid, a new radioactive product is obtained, mixed with ferric chloride. The new product is the immediate parent-substance of uranium X, into which it gradually changes, and is an intermediate product in the formation of uranium X from uranium. Its complete separation from uranium offers considerable difficulty.—E. F.

PATENTS.

Formic acid; Method for manufacturing — W. A. Dyes, Manchester. From A. Hempel, Leipzig-Plagwitz, Germany. Eng. Pat. 3428, Feb. 15, 1908.

FORMIC acid is manufactured by heating formates *in vacuo* with acids or acid salts, such as strong sulphuric acid, bisulphate, or pyrosulphate, the acid or acid salt being added in small portions, as the distillation proceeds. This method decomposition of the formic acid is prevented.—F. SONX.

Pinene hydrochloride; Treatment of liquid or oily and obtainment of solid pinene hydrochloride and camphene therefrom. W. H. Bentley, C. Weizmann, and Clayton Aniline Co., Manchester. Eng. Pat. 7319, Apr. 2, 1908.

In the production of pinene hydrochloride, the solid

product, which is useful for the manufacture of camphene, is always accompanied by a liquid, oily product, which is not suitable for that purpose. This liquid contains a considerable quantity of the solid hydrochloride in solution. The latter constituent may be recovered by oxidising the oily impurity by heating with dilute nitric acid (25 per cent.). An alternative process consists in polymerising the oily impurity with concentrated or fuming sulphuric acid at a temperature not exceeding 40° C. The liquid is converted into a polyterpene from which the solid hydrochloride may be separated by extraction with petroleum. A third method consists in heating the oil with a solution of an alkali or earthy hydroxide at a temperature of about 240° C., and fractionating the product after distillation with steam; in this case camphene is obtained directly.—J. F. B.

Hydro-aromatic alcohols or thymol and salicylic esters;

Process for preparing mixed carbonates of — Farbenfabr. vorm. F. Bayer und Co. Ger. Pat. 206,055, Dec. 15, 1907.

THE compounds, which possess all the therapeutic properties of their constituents, are obtained (1), by the action of the carbonate or chlorocarbonate of a hydro-aromatic alcohol or of thymol on salicylic esters; (2), by the action of the chlorocarbonate of a salicylic ester on a hydro-aromatic alcohol or thymol; (3), by treating a mixture of a salicylic ester and the alcohol with phosgene.—T. F. B.

Salicylic acid compounds; Process for preparing readily absorbed, non-irritant — N. Sulzberger and L. Spiegel. Ger. Pat. 206,056, May 4, 1906.

COMPOUNDS which have antiseptic properties, and which do not irritate the skin, are obtained by the action of fatty acids, containing not more than 12 carbon atoms, on salicylic acid or its derivatives in which the hydroxyl group is free. Thus, oleylsalicylic ethyl ester is obtained by heating sodium oleate with ethyl salicylate, in presence of phosphorus oxychloride, to 100° C.—T. F. B.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

PATENTS.

Sensitised surfaces or films for photographic purposes;

Production of — W. H. Caldwell, Inverness, Eng. Pat. 1689, Jan. 24, 1908.

THE object of this invention is to produce sensitive surfaces on which images can be produced either by long exposure only, or by short exposure and subsequent development. To attain this result, a substance must be present which is not reduced by light after its oxidation by the liberated halogen; which will not reduce the silver salt used, in the dark; and which will absorb the halogen as rapidly as it is set free by light. Certain salts of hydrazine and hydroxylamine or their derivatives fulfil these conditions, such as hydrazine sulphate, sulphite, or phosphate, or a salt of a fatty hydrazine or hydroxylamine; when a colloid emulsion is used, formylhydrazine may be employed. The substances named may be added to the emulsion before its application to the support, or an ordinary plate, film, or paper may be immersed in a solution of the substance.—T. F. B.

Grained screens for making colour photographs; Manufacture of — C. L. A. Brasseur, Orange, N.J., U.S.A.

Eng. Pat. 18,750, Sept. 7, 1908. Under Int. Conv., Sept. 9, 1907.

A PAPER or other support is coated with an adhesive substance, which is allowed to dry; a number of grains of celluloid or other transparent substance, of different light-selection properties, are applied to the support, which is then rendered adhesive and allowed to dry; the excess of grains is removed, and the adhering grains are transferred to a transparent support, *e.g.*, of celluloid, and subjected to heat and pressure, to flatten them out;

a thin solution of celluloid is sprayed on the surface, and the film is polished between hot metal plates. (See also McDonough, this J., 1892, 937, and Lumière, this J., 1905, 104.)—T. F. B.

Polychrome screens for colour photography: Method of making —. C. L. A. Brasseur, Orange, N.J., U.S.A. Eng. Pat. 20,909, Oct. 3, 1908. Under Int. Conv., Oct. 4, 1907.

A SUPPORT is covered, in portions of its surface, such as in dots, with an adhesive; coloured grains are dusted on it, the excess removed when the adhesive is dry, and the remainder of the surface is similarly treated with grains of one or more other colours.—T. F. B.

Colour screens for colour photography or like purposes: Process for making —. Verein. Kunstseide-Fabr., A.-G., Kelsterbach a/M., Germany. Eng. Pat. 21,839, Oct. 15, 1908. Under Int. Conv., July 13, 1908.

SHEETS of celluloid or other suitable transparent, plastic material, are impressed in an etched metal line matrix, when a series of parallel recesses is formed on the sheet. The surface is printed with printer's ink, and the sheet, after the back has been suitably insulated, is stained with an alcoholic solution of a suitable dyestuff; the ink is now removed, and the surface of the sheet printed with a second colour. If it is desired to make three or more colour screens, the sheets are again impressed with an etched matrix, the resulting recesses being at right angles to the first set, and the process repeated.—T. F. B.

Photographs on plates, films, etc., with colour screens: Process for obtaining — in artificial light. G. Krebs, Fr. Pat. 304,067, Sept. 9, 1908.

COMPOSITIONS for producing artificial light for use in taking colour photographs through screens are composed of aluminium and magnesium powders, together with salts of copper, barium, cesium, indium, and thallium, amorphous phosphorus, or other substances giving green, blue, or violet colours to the flame. In using these lighting compositions, the screens are coloured with tartrazine.—T. F. B.

XXII.—EXPLOSIVES, MATCHES, &c.

Safety explosives: Tests with —. Beyling, Glückauf, 1909, 45, 109—115.

At Gelsenkirchen, safety explosives are now tested against firedamp alone, and against coal dust alone, instead of as previously against a mixture of the two (see this J., 1909, 42). The experiments were carried out in the manner previously explained, the cartridges being 35 mm. in diameter. They were fired without stemming from a mortar with a 55 mm. borehole. The explosive mixture consisted of 8 to 9 per cent. of firedamp mixed with air, and in the case of the coal dust experiments, 12 litres of fine coal dust were used, 10 litres being spread upon the floor of the gallery, whilst the other 2 litres were kept in motion in the chamber. In all, 27 different explosives were tested and the author gives in tabular form the composition of these explosives and the weight of each which either does or does not ignite the coal dust and firedamp respectively. In some cases the maximum charge which would go into the borehole was employed. In the case of other more powerful explosives, it was not considered safe to work with the maximum charge, on account of the possibility of over-straining the gun. A lesser weight was consequently used. In both instances the quantity of explosive causing ignition was therefore not actually determined.

The new explosives which have been tested are much better than the old, from the point of view of safety, but have the disadvantage of being less powerful. It is hardly possible to alter this, and therefore the less powerful explosives should be used only at those points of the mine where safety blasting agents must be

employed. One noticeable feature is that a considerable proportion of the explosives tested contained very large percentages of sodium chloride or potassium chloride, or a mixture of the two. There seems to be no doubt that sodium chloride is of very considerable advantage as regards increasing the safety of an explosive, with a coal dust mixture. This is strikingly shown in the following instance:—

150 grms. of *Carbonite No. 1* exploded the coal dust mixture, whilst 635 grms. of *Carbonite 1A* were fired in the mixture without igniting it. As will be seen from the composition of these two explosives, it is to the presence of sodium chloride that this increased feature of safety must be attributed. *Carbonite No. 1*: Nitroglycerin (25.0), sodium nitrate (30.5), flour (39.4) and potassium bichromate (5.0 parts). *Carbonite 1A*: Nitroglycerin (21.0), sodium nitrate (30.0), flour (38.0) and sodium chloride (7.0 parts).

The following explosives, as typical of some of the results, have been selected from the list given:—

Gesilit No. 1: Nitroglycerin jelly (30.75), dinitrotoluene (5.25), sodium chloride (7.0), sodium nitrate (18.0) and dextrin (39.0 parts).

Gesilit No. 2: Nitroglycerin jelly (30.75), dinitrotoluene (5.25), ammonium nitrate (22.0), sodium chloride (21.0) and dextrin (21.0 parts).

Kohlensilesia 4A: Potassium chlorate (80.0), resin (16.0) and nitrated resin (4.0 parts).

Fördit 1C: Nitroglycerin (24.5), collodion cotton (1.0), nitrotoluene (31.0), flour (2.0), dextrin (2.0), glycerin (5.5), ammonium nitrate (32.0) and potassium chloride (30.0 parts).

Verstärktes Chromammonit: (Reinforced chromammonite), Ammonium nitrate (70.0), potassium nitrate (10.0), tri-nitrotoluene (12.5), chrome ammonium alum (7.0) and vaseline (0.5 parts).

ERRATUM.

This Journal, 1906, 560, col. 2, line 16 from bottom. For "Mommi," read "Monni."

PATENT.

Wrappers for blasting explosives. Kynoch, Ltd. Birmingham, and J. P. Udall, Walmley, Warwick. Eng. Pat. 9259, April 29, 1908.

THE object of the invention is to reduce the amount of material (the "turnover") on the end of a blasting explosive cartridge, which forms an objectionable waste between the ends of successive cartridges in a bore-hole. The sides of the wrapper (which form the ends when it is wrapped round the cartridge) are cut so as to taper instead of being parallel; the narrow end of the taper is only the length of the cartridge, and at the other end it is this length plus allowance for turnover. Thus the total amount of paper in the turnover is exactly half that resulting with an ordinary wrapper having parallel edges.—F. SOBX.

XXIII.—ANALYTICAL CHEMISTRY.

APPARATUS.

PATENTS.

Pyknometer. W. R. Bousfield, Hendon, Middlesex. Eng. Pat. 4861, Mar. 3, 1908.

THE apparatus consists of twin cylindrical vessels, the conical upper ends of which communicate by tubes of fine bore with conical cups closed by stoppers. These twin vessels are connected together near their lower ends by a short tube and higher up by a handle which serves to suspend the apparatus in a thermostat. The instrument is used in the ordinary way, and the level is finally observed with a magnifying glass, to ascertain when a constant temperature has been attained; it is filled by suction, and air bubbles are readily removed by working the liquid backwards and forwards. Before removal from the thermostat, the cups are wiped out with a suitably shaped swab. The advantages claimed for the apparatus are: (1), its suitability for use at temperatures above or below that of weighing; (2), the great accuracy of the results obtained; (3), the readiness with which air bubbles are removed; and (4), its lightness and strength. (See Chem. Soc. Trans., 1908, 93, 679.) —F. SODN.

Calorific value of gases; Methods of and devices for determining the —. F. P. Schönberger, Sagn, Germany. Eng. Pat. 2314, Feb. 1, 1908.

EE Fr. Pat. 386,294 of 1908; this J., 1908, 715.—T. F. B.

INORGANIC—QUANTITATIVE.

Lead; Determination of — by the peroxide method. W. S. Medell, Eng. and Min. J., 1909, 87, 262. (See also Ericson, this J., 1908, 860.)

5 GRM. of the ore is decomposed with 10 c.c. of sulphuric acid (1:1) and 5 c.c. of a mixture of hydrochloric and nitric acids, and evaporated till fumes of sulphuric anhydride are evolved. If manganese be present, a few crystals of sodium sulphite are added to reduce any manganates. The assay is cooled and filtered, decanting as far as possible and washing several times with sulphuric acid. Six lots of 15 c.c. of a hot 3 per cent. solution of caustic soda are passed through the filter and caught in the vessel containing the residues, the filter being then well washed with hot water. The solution is boiled to dissolve the lead sulphate, cooled to 90° C., and 15 to 35 c.c. of 5 per cent. solution of potassium bromide, saturated with bromine, added. The solution is heated nearly to boiling, the constant stirring for 5 minutes, and set aside to settle, care being taken that the excess of bromine is not boiled off. It is then decanted through a filter and the paper washed once with cold water. The precipitate is washed by decantation, with three lots of 25 c.c. of water, and the filter transferred to the beaker containing the residue, and 250 c.c. of water and 5 c.c. of orthophosphoric acid added. Standard ferrous ammonium sulphate solution is added in excess to dissolve the peroxide, excess being titrated back with standard potassium permanganate solution. The ferrous ammonium sulphate solution contains 18.958 grms. per litre, 1 c.c. serving to reduce 0.005 grm. of lead from the peroxide to the monoxide. A permanganate solution contains 1.528 grms. per litre. The method is said to be short, accurate, and not affected by contaminating elements.—F. R.

Stannic acid, chromic acid, and iron; Determination of — in the presence of each other. G. Edgar, Amer. Sci., 1909, 27, 174—178.

STANNIC acid, chromic acid, and iron (ferrie) may be accurately determined in the presence of each other by the iodometric method already described (this J., 1908, 1057), provided that the chromium is determined separately by reduction with arsenious acid; for the ferrie salt is unaffected in the first distillation and is reduced by the hydriodic acid in the second. The process

is carried out, therefore, as previously indicated (*loc. cit.*), and, in another portion of the solution the chromic acid is determined by slightly acidifying with sulphuric acid, adding 3 c.c. of syrupy phosphoric acid, to precipitate the iron, and an excess of standard arsenious acid, beyond that required by the chromic acid; the solution is allowed to stand for 15—20 mins., and is then made alkaline with sodium bicarbonate, and an excess of standard iodine solution added; after standing further for from 30 minutes to an hour in a stoppered flask, the excess of iodine is removed by arsenious acid and the titration finished with iodine.—F. SODN.

Phosphoric acid; Determination of — by a colorimetric method. I. Ponget and D. Chouchak, Bull. Soc. Chim., 1909, 5, 104—109.

THE method is based on the insoluble character of the precipitate formed by the action of phosphomolybdic acid on strychnine. A very sensitive reagent is made by mixing 2.5 c.c. of pure nitric acid with 10 c.c. of a 15 per cent. solution of sodium molybdate, and then adding 1 c.c. of a cold saturated solution of strychnine sulphate. With only 0.005 mgrm. of phosphoric acid per 100 c.c., this reagent, which should be freshly prepared and perfectly clear, gives an opalescence which continues to develop for about 20 minutes. For the determination, a solution of the substance (containing 0.01 to 0.05 mgrm. of phosphoric oxide) in nitric acid is prepared, and this is evaporated to dryness on the water-bath; the cold residue is taken up by 10 c.c. of 35 per cent. nitric acid, the mixture shaken at intervals for 20 minutes, and the liquid then decanted or filtered through a small filter which has been washed with nitric acid and water; the volume of liquid is brought up to about 47 c.c. by washing, the liquid shaken, mixed with 2 c.c. of the reagent, and the mixture made up to 50 c.c. As a standard, 10 c.c. of nitric acid (35 per cent.) are added to 3 c.c. of a solution of phosphoric acid containing 10 mgrms. of phosphoric oxide per litre, water is added to about 47 c.c., and then, after shaking, 2 c.c. of the reagent are added and the volume made up to 50 c.c. After standing for 20 minutes a colorimetric comparison of these solutions is made, the opalescence showing in the colorimeter as a yellowish-brown tint, and the depths of the two liquids giving equal tints are taken as inversely proportional to the amounts of phosphoric acid present. The method gives accurate results with very small quantities of phosphoric acid, and the presence of calcium, iron, magnesium, aluminium, potassium, and sodium does not affect the determination, unless their amount is very large in comparison with that of the phosphoric acid. It is applicable to the analysis of such substances as water, soils, manures, and iron (containing more than 0.03 per cent. of phosphorus). Arsenic should not be present in larger proportion than 2—3 times that of the phosphorus. When very large quantities of other elements are present, the phosphoric acid may first be separated from the acid solution by adding a ferric salt and calcium carbonate, and the precipitate obtained then dissolved and the solution dealt with as above.—F. SODN.

Phosphates; Determination of — colorimetrically. C. Estes, J. Amer. Chem. Soc., 1909, 31, 247—250.

IN the determination of phosphates by the colorimetric method with ammonium molybdate, the intensity of the colour obtained, is very materially influenced by the presence of certain salts. The extent of this influence has been studied with the salts mentioned below, and the results show that the error in reading does not exceed 5 per cent. with a maximum of:—5 parts of sodium sulphate (decahydrate), 10 parts of potassium nitrate or magnesium sulphate (hydrate), 15 parts of potassium hydrogen sulphate, 20 parts of calcium nitrate, magnesium nitrate, or sodium chloride, 30 parts of potassium ethyl sulphate, or 50 parts of sodium nitrate per 10,000 of the solution. —F. SODN.

XXIV.—SCIENTIFIC & TECHNICAL NOTES.

Colloids; Extension of the idea of "solubility" to —. J. Duclaux. *Compt. rend.*, 1909, **148**, 295—297.

THE ordinary conception of a saturated solution is not applicable to colloids, but their "solubility" may be defined by another method. If a solution be enclosed in a vessel, the walls of which are permeable by the solvent but not by the solute, and subjected to a pressure higher than the osmotic pressure, the solvent will filter through the walls and the concentration of the solution will increase up to a limit. The pressure at which the solvent ceases to pass away and the colloid becomes solid, is called the "maximum osmotic pressure" and the concentration of the colloid at the limit, represents its "solubility." At the ordinary temperature, the "solubility" of gelatin is about 4 per cent., that of gelose, less than 1 per cent., whilst certain preparations of ferric hydroxide and of tungstic acid remain soluble up to 60 per cent. The maximum pressure of Predig's platinum solution is less than 2 cm. of water, whilst that of ferric hydroxide exceeds 20 m. The principle is useful for defining and measuring certain properties appertaining to colloidal solutions. *Stability.*—The stability of a colloidal solution is proportional to its maximum pressure or maximum "solubility," and may thus receive numerical expression. *Variability.*—When a coagulating substance is added to a solution of a colloid in quantity insufficient to induce coagulation, it modifies the properties of the solution either visibly or invisibly. Such modification is immediately indicated by a lowering of the maximum osmotic pressure of the solution. *Fractionation.*—In certain cases it is possible to effect a partial separation of two colloids in solution, when they have very different maximum osmotic pressures. Such separations, however, are never complete, and as a general rule, all colloids may be regarded as isomorphous. *Classification.*—The determination of the maximum osmotic pressure affords a ready means of describing a series of colloids of the same order. For instance, a very wide range of maximum pressures is shown by the various modifications of starch, of colloidal gold, and of ferric hydroxide. The basis of the phenomena of "solubility" and of maximum osmotic pressure, appears to lie in the properties of the micella itself, and is closely dependent on the size, the chemical composition, and particularly the electrical charge of the latter. Thus, one of the fundamental properties of the colloidal state is brought within the range of experimental expression.

—J. F. B.

Benzene ring [Tyrosine, etc.]; Introduction of iodine into the —. A. Oswald. *Z. physiol. Chem.*, 1909, **58**, 290—294.

WHEN a solution of albumin is treated with a solution of iodine in potassium iodide, a dark brown precipitate of an iodine derivative is gradually formed; the presence of a small amount of alkali is favourable. The product is a periodide, which readily parts with a portion of its iodine. After treatment with thiosulphate and washing, a nearly colourless product remains, which contains from 10 to 14 per cent. of combined iodine, according to the

nature of the original protein. The reaction has been ascribed to the presence of tyrosine in the protein molecule, but it is not peculiar to tyrosine, since other proteins, such as gelatin, which contain no tyrosine group, also combine with iodine. The author has made experiments in order to see whether other products of the hydrolysis of proteins containing benzene derivatives were capable of entering into combination with iodine. Experiments with phenylalanine led to negative results. On the other hand a large number of phenolic bodies readily yielded iodine derivatives when treated with iodine in presence of alkali. The author enunciates the general rule: that the presence of a hydroxyl group in the benzene nucleus imparts to the latter the property of combining readily with iodine, whilst benzene derivatives which contain no hydroxyl groups do not possess this property. The property of combining readily with iodine is also possessed by pyrrole derivatives, e.g., in the case of tryptophane, also by combined pyrrol derivatives, e.g., indole; pyrrole itself yields tetra-iodopyrrole under the above-mentioned conditions.—J. F. B.

Peroxydase; Action of acids on —. G. Bertrand and M. Rozenband. *Compt. rend.*, 1909, **148**, 297—300.

IN a previous paper (this J., 1907, 983) it was shown that traces of certain acids have a powerful inhibitory effect on the oxidising action of laccase, and that quantitatively their action is proportional to their molecular weight and inversely to their degree of basicity; the action also affords a quantitative idea of the activity of the electro-negative group attached to the manganese. The authors have now studied the action of acids on the activity of a preparation of peroxydase obtained from wheat, measuring this activity by the orange coloration developed by the ferment in a solution of guaiacol and hydrogen peroxide. In this case the acids could not be divided into two groups, one active and the other inactive, as in the case of laccase. According to their inhibitory action on peroxydase, the various acids may be arranged in a continuous series, the order of which corresponds approximately with that of their electrical conductivities, or perhaps rather of their catalytic activities. On setting out in one table the relative inhibitory power of several of the acids towards peroxydase, and in another table their relative inverting power on sucrose, it is noticed that the order is the same in both tables, but that the numerical proportions are different for the two kinds of action. There is, therefore, some disturbing influence, and this perhaps explains the fact that certain other acids do not show an approximate relationship between the two kinds of activities. This disturbing factor may possibly be the presence of neutral salts, which modify the degree of influence of the acids, so that the inhibitory effect depends not only on the acid function, but also to a large extent on the radical to which this function is attached. Lastly, the authors conclude, from the difference in the inhibitory action of acids, that the oxidising action of peroxydase is probably regulated by a very different mechanism from that of tyrosinase and laccase.—J. F. B.

Amylase; Presence of — in old grain. Brocq-Rousseau and E. Gain. *Compt. rend.*, 1909, **148**, 359—361.

GRAINS of wheat, 50 years old, which had lost their germinating power, were found to still contain diastases (dextrinase and amylase) capable of transforming starch into sugar.—E. F.

New Books.

THE MANUFACTURE OF EXPLOSIVES. TWENTY YEARS' PROGRESS. Four Cantor Lectures delivered at the Royal Society of Arts in November and December, 1908. By OSCAR GUTTMANN. Whittaker and Co., 2, White Hart Street, Paternoster Square, London, E.C., and 64 and 66, Fifth Avenue, New York, 1909. Price 3s. net.

Svo volume, containing 80 pages of subject-matter, with coloured frontispiece and 11 illustrations in the text, and an alphabetical index. The matter of the four lectures is classified as follows:—I. State of the Art in 1886. Black powder, or other nitrate mixtures. Chlorate mixtures. Picric acid and picrates, &c. II. Manufacture of nitro-glycerine, Dynamites, Guncotton, Nitrostarch, &c. III. Smokeless powders: History; Manufacture; Flameless powders; Safety explosives; Coal dust; Safety explosives in practice. IV. Use of nitrocellulose for celluloid, artificial silk and varnish; Machinery driven by explosives; Factories, their construction, &c.; Merits and demerits of explosives; Stability and its proof; Stabilisers; Accidents with smokeless powder; &c.

ZWANZIG JAHRE FORTSCHRITTE IN EXPLOSIVSTOFFEN. Vier Vorträge gehalten in der Royal Society of Arts in London. November—Dezember, 1908. Von OSCAR GUTTMANN. Julius Springer's Verlag, Berlin, 1909. Price M. 3.

The same work in German.

PHYSIKALISCHE CHEMIE DER METALLE. Sechs Vorträge über die wissenschaftlichen Grundlagen der Metallurgie. Von Dr. RUDOLF SCHENCK, Professor der Physik. Chemie an der Tech. Hochschule zu Aachen. Wilhelm Knapp's Verlag, Halle a. S. 1909. Price M. 7.00.

LARGE Svo volume, containing 183 pages of subject-matter with 114 illustrations, an index to literature referring to all the six lectures, and alphabetical indexes of names and subjects. The subject-matter of the lectures is classified as follows:—I. Alterations of form; Electrical and optical properties of the metals; Theory of electrons. II. Metallic solutions and alloys. III. Alloys of metals with carbides, oxides, sulphides. Iron and steel; Phase rule. IV. Metallurgical reactions. Oxidation and reduction. V. Decomposition of carbon monoxide; Blast furnace process. VI. Reactions of the sulphides.

ON THE CALCULATION OF THERMO-CHEMICAL CONSTANTS. By H. STANLEY REDGROVE, B.Sc. Edward Arnold, 41 and 43, Maddox Street, London, W. 1909. Price 6s.

Svo volume, containing 99 pages of subject-matter, including an appendix of 4 pages, criticising Thomsen's method of calculating the thermal constants of organic substances. The work closes with an alphabetical index of the substances referred to in the text. The text is classified as follows:—I. Calculation of physico-chemical

constants. II. Calculation of thermo-chemical constants. (i.), Thermal constants of the hydrocarbons. (ii.), Thermal constants of organic halogen compounds; of organic oxygen compounds. (iii.), Thermo-chemical evidence for von Baeeyer's strain theory. (iv.), Thermal constants of organic sulphur compounds; and of organic nitrogen compounds. (v.), Summary and Conclusion.

A COMPENDIUM OF FOOD-MICROSCOPY, WITH SECTIONS ON DRUGS, WATER, AND TOBACCO. Compiled, with additions and revision, from the late Dr. A. H. HASSALL'S works on Food. By EDWY GODWIN CLAYTON. Baillière, Tindall and Cox, 8, Henrietta Street, Covent Garden, London. 1909. Price 10s. 6d. net.

8vo volume, containing 391 pages of subject-matter, with a frontispiece, and 282 plates and illustrations, followed by a glossary of terms, a bibliographic list of works of reference, list and index of illustrations, and the alphabetical index. The subject-matter receives the following arrangement:—I. Foods derived from vegetable sources. II. Foods derived from animal sources. (i.), Flesh. (ii.), Animal parasites which infest flesh. (iii.), Fish. (iv.), Milk and cream. (v.), Butter. (vi.), Cheese and cheese mites; Lard; Isinglass; Gelatin. III. Tobacco, Drugs, Bitters, and Colouring matters. IV. Water.

THE EVERYDAY USES OF PORTLAND CEMENT. The Associated Portland Cement Manufacturers, Ltd., Portland House, Lloyd's Avenue, London, E.C. 1909. Price 2s. 6d. net.

8vo volume, containing 156 pages of subject-matter, and 148 illustrations, the table of contents at the beginning serving as an index. The subject-matter is classified under the following heads:—I. Portland cement. II. Aggregates. III. Concrete. IV. Memoranda for concrete users. V. Workmanship. VI. Reinforced concrete. VII. Concrete blocks and moulded concrete. VIII. Various uses of concrete. IX. Some novel uses of concrete.

INTERNATIONAL CATALOGUE OF SCIENTIFIC LITERATURE. Sixth Annual Issue. D. CHEMISTRY. Harrison and Sons, 45, St. Martin's Lane, London, W.C. Price 37s. 6d.

8vo volume of 1078 pages, being an index of the chemical literature of 1906; the various works are indexed both under authors' names and subjects, the subjects catalogue being divided into sections, in each of which the final arrangement is in the alphabetical order of authors' names. There are also subject indexes in English, French, German, and Italian.

COAL TABLES, 1907. Parly. Paper No. 377. Wyman and Sons, Fetter Lane, E.C. Price 6d.

THIS return contains statistical tables relating to the production, consumption, and imports and exports of coal in the British Empire and the principal foreign countries in each year from 1885 to 1907, as far as the particulars can be stated; together with statements showing the production of lignite and petroleum in the principal producing countries for a series of years (in continuation of Parliamentary Paper No. 349, of Session 1907).

Patent List.

Where a Complete Specification accompanies an Application, an asterisk is affixed. The dates given are (i) in the case of Applications for Patents, the dates of Application, and (ii) in the case of Complete Specifications Accepted, those of the Official Journals in which acceptances of the Complete Specifications are advertised.

Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

I.—PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

3757. Tebbutt. Treatment of materials by disintegration or pulverisation.* Feb. 15.
3922, 3923, and 3924. Dawkins (McLeod). Centrifugal separators.* Feb. 17.

4057. Peake. Electrical pyrometers. Feb. 19.
4089. Horner. Drying ovens.* Feb. 19.
4107. Elliott. Apparatus for purifying fumes and gases. Feb. 19.
4183. Longsdon and Bottomley. Centrifugal drying machines or hydro-extractors. Feb. 20.
4325. Marks (John Kommanditges, Maschinenbauanst.). Centrifugal apparatus for separating purposes.* Feb. 22.
4330. Love. Furnaces. Feb. 22.
4358. Sherwood. Filtering apparatus. Feb. 22.
4604. Vallat. *See under XVII.*
4701. Schlicht. Dehydrating peat and the like, and apparatus therefor. Feb. 25.

COMPLETE SPECIFICATIONS ACCEPTED.

3685 (1908). Place. *See under VII.*
5685 (1908). Davey and Davey. Treating brine or other chemical to be concentrated, evaporated, or distilled, and the manufacture of vegetable black. Feb. 24.
13,360 (1908). Dixon and Middleton. Pyrometers. March 3.
16,047 (1908). Aktiebolaget Separator. Continuous strainer. Feb. 24.
17,756 (1908). Arbuckle and Osborne. Separating comminuted ore and other solid from liquids. Feb. 24.
25,323 (1908). Flick. Distilling apparatus. Feb. 24.

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

3809. Green. Mantles for incandescent gas lighting. Feb. 16.
3918. Hutchins. Gas producers. Feb. 17.
3951. British Thomson-Houston Co. (General Electric Co.). Manufacture of incandescent electric lamp filaments.* Feb. 17.
3981. Gutensohn. Manufacture of combustible briquettes. Feb. 18.
4164. British Thomson-Houston Co. (General Electric Co.). Manufacture of filaments or conductors of refractory material suitable for electric lamps.* Feb. 19.
4375. Conran. Distillation of coal and by-products resulting therefrom. Feb. 22.
4792. Koppers. Preserving coke-oven walls. [Ger. Appl., March 11, 1908.]* Feb. 26.

COMPLETE SPECIFICATIONS ACCEPTED.

1409 (1908). Seymour. Coke ovens. March 3.
6047 (1908). Coke Ovens and By-Products Co., and Wellington. Coke ovens. March 3.
8186 (1908). Wellington and Everest. Manufacture of gas. Feb. 24.
12,856 (1908). Seaby-Smith. *See under X.*

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, PETROLEUM, AND MINERAL WAXES.

APPLICATIONS.

4375. Conran. *See under II.*
4604. Vallat. *See under XVII.*

COMPLETE SPECIFICATION ACCEPTED.

25,318 (1908). Thompson (Lingner). Manufacture of condensation products of wood tar with formaldehyde. March 3.

IV.—COLOURING MATTERS AND DYE-STUFFS.

APPLICATIONS.

3758. Meister, Lucius, und Brüning. Manufacture of dyestuffs. [Ger. Appl., Aug. 31, 1908. Addition to No. 3602 of 1909.]* Feb. 15.
4767 and 4678. Newton (Bayer and Co.). Manufacture of azo dyestuffs. Feb. 26.
4859. Wülfing, Dahl, and Co. Azo dyes. [Ger. Appl., Feb. 13, 1909.]* Feb. 27.

COMPLETE SPECIFICATIONS ACCEPTED.

- 5582 (1908). Newton (Bayer und Co.). Manufacture of indigo compounds. Feb. 24.
 7418 (1908). Badische Anilin und Soda Fabrik. Manufacture of colouring matters of the anthracene series. Feb. 24.
 20,094 (1908). Imray (Soc. Chem. Ind. in Basle). Manufacture of sulphurised vat dyestuffs of the anthracene series. March 3.

V.—PREPARING, BLEACHING, DYEING, PRINTING, AND FINISHING TEXTILES, YARNS, AND FIBRES.

APPLICATIONS.

3670. Rhodes. Apparatus for treating with liquids wool yarn and other fibrous materials. [Addition to No. 17,038 of 1908.]* Feb. 15.
 3719. Ransford (Cassella and Co.). Production of two-coloured effects on mixed fabrics. Feb. 15.
 3871. Gates and Gates. Dye jigs. Feb. 17.
 4104. Friedrich. Producing solutions for spinning artificial threads, etc. [Ger. Appl., Feb. 19, 1908.]* Feb. 19.
 4362. Courtanld and Gilles. Manufacture of crepe. Feb. 22.
 4683. Ellis (Heberlein et Cie.). Mercerising textile fabrics.* Feb. 25.
 4757. Hart. Dyeing yarns and fabrics with pigments. Feb. 26.
 4799. McDonough. Wool scouring and drying machine. [Australian Appl., Aug. 22, 1908.]* Feb. 26.

COMPLETE SPECIFICATION ACCEPTED.

- 759 (1908). Malard. Treating textile and other materials by liquid processes. Feb. 24.

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

3650. Thwaites and Ralph. Treating liquors containing metallic compounds. Feb. 15.
 3704. Davidson. Fire-extinguishing compounds.* Feb. 15.
 3732. Larsen. Manufacture of silicon nitride. [Appl. in Norway, Feb. 17, 1908.]* Feb. 15.
 3939. Vautin. Treatment of neutral nitrates. Feb. 17.
 3959. Eijzman. Purification of sea-water or brine for separating salts. [Comprised in No. 11,388, May 26, 1908.]* Feb. 18.
 4167. Thwaites and Ralph. Treating and utilising liquors containing copper. Feb. 20.
 4224. Bowen. Apparatus for dearsenicating sulphuric or other acid. Feb. 20.
 4465. Barton. Manufacture of certain lead oxides or salts. Feb. 23.
 4494. Beskow and Ekedahl. Removing superphosphate from decomposition chambers. [Swed. Appl., March 2, 1908.]* Feb. 23.
 4763. Thomas and Davies. Production of oxalic acid. Feb. 26.
 4872. Chem. Fabr. Bettenhausen Marquart und Schulz. Production of a permanent ammoniacal solution of cupric acid. [Ger. Appl., March 25, 1908.]* Feb. 27.
 4876. Higgins. Manufacture of sulphite and sulphate of ammonia. Feb. 27.

COMPLETE SPECIFICATIONS ACCEPTED.

- 3685 (1908). Place. Apparatus for liquefying air. Feb. 24.
 3740 (1908). Ward, and Barnstone Blue Lias Lime Co. Lime kilns. Feb. 24.
 3902 (1908). Dyes (Hempel). Manufacture of calcium oxalate. Feb. 24.
 3904 (1908). Dyes (Hempel). Manufacture of oxalic acid. Feb. 24.
 4897 (1908). Dyes (Hempel). Manufacture of formates and oxalates. March 3.
 5502 (1908). Goodwin and Burgess. Generation of ozone. Feb. 24.
 5685 (1908). Davey and Davey. *See under I.*

9725 (1908). Weiss. *See under XXIII.*

- 11,865 (1908). Newton (Bayer und Co.). Manufacture of alkali hydrosulphites. Feb. 24.
 15,554 (1908). Brünler. Producing an air mixture of a high ratio of oxygen from the atmosphere. March 3.
 18,434 (1908). Gibbs. Manufacture of chromates and aluminates. Feb. 24.
 20,199 (1908). Johnson (Badische Anilin und Soda Fabrik). Manufacture of stable, anhydrous hydrosulphites. Feb. 24.

VIII.—GLASS, POTTERY, AND ENAMELS.

APPLICATION.

4819. Lees. Abrasive or polishing material.* Feb. 27.

COMPLETE SPECIFICATIONS ACCEPTED.

- 3255 (1908). Hadlington and Webster. Regenerative gas-fired kilns for pottery, tiles, etc. Feb. 24.
 3485 (1908). Keppeler and Spangenberg. Treatment of clay, kaolin, or ceramic masses. Feb. 24.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

4048. Claypoole. Hard agglomerate material and process for producing same.* Feb. 18.
 4512. Williams and Morris. Fire cements. Feb. 24.

COMPLETE SPECIFICATION ACCEPTED.

- 4579 (1908). Lavery. Continuous kilns for burning brick and the like. March 3.

X.—METALS AND METALLURGY.

APPLICATIONS.

3915. Kirk. Manufacture of iron, steel, and other metals. Feb. 17.
 3925. Bennett (Hormenkoi). Gold retort. Feb. 17.
 4153. Vautin. Concentration of copper ores. Feb. 19.
 4257. De Wyckoff. Alloy for use in making bullets, projectiles, etc.* Feb. 20.
 4342. Vautin. Wet separation of copper from its ores or compounds. Feb. 22.
 4357. Isherwood. Treatment of refractory lead zinc ores. Feb. 22.
 4471. Hemingway. Recovering lead and zinc from compounds. Feb. 23.
 4531. Martin. Separation of complex ores. Feb. 24.
 4558. Soc. Franç. Electrolytique. Extraction of metals from their ores. [Fr. Appl., Feb. 25, 1908.]* Feb. 24.
 4563. Howard and Hadley. Treating the fumes from zinc retorts. Feb. 24.
 4574. Soc. Franç. Electrolytique. Extraction of copper and analogous metals from ores and alloys. [Fr. Appl., Feb. 25, 1908.]* Feb. 24.
 4641. Industrial and Mineral Research Synd., Ltd., and Moeller. Separating metal combinations from the gangue of minerals and from each other by electro-magnets. Feb. 25.
 4667. Lysaght, Ltd., and Beddoe. Zinc condensers. Feb. 25.
 4805. Francis. Treatment of finely-divided ores.* Feb. 26.
 4914. Rouse. Preparation of copper ore concentrates for smelting. Feb. 27.

COMPLETE SPECIFICATIONS ACCEPTED.

- 3651 and 3652 (1908). Casterline. Hardening and tempering steel. Feb. 24.
 4142 (1908). Foniakoff. Agglomeration of small finely-divided ores. March 3.
 4424 (1908). Harbord. Drying blast for metallurgical furnaces. Feb. 24.
 12,452 (1908). Lamon and Thomas. Improving the physical properties of metals and their alloys. Feb. 24.
 12,856 (1908). Seely-Smith. Gas producers for use in the manufacture of steel. Feb. 24.
 16,428 (1908). Mennicke. Preparing, smelting, and utilising products containing tin, especially the sponge and

slime obtained in electrolytic removal of tin from tin-plate scrap. March 3.

- 16,521 (1908). Hughes. Metallurgical furnaces. March 3.
17,756 (1908). Arbuckle and Osborne. *See under I.*

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

APPLICATIONS.

4175. Ruthenburg. Electrodes for electric furnaces. Feb. 20.
4553. Aktiebolaget Elektrometall. Electric furnace. [Swed. Appl., March 10, 1908.]* Feb. 24.

COMPLETE SPECIFICATIONS ACCEPTED.

- 13,134 (1908). Usine Genevoise de Dégrossissage d'Or. Electrolytic cells for separating the constituents of a mixture of metals or an alloy. Feb. 24.
16,428 (1908). Mennicke. *See under X.*
21,234 (1908). Lutz. Electroplating. Feb. 24.

XII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, Etc.

(A.)—PIGMENTS, PAINTS.

APPLICATIONS.

3744. Bellé. Apparatus for making artificial ultramarines.* Feb. 15.
4040. Jagenberg. Production of printing-ink and oil paints. [Ger. Appl., Feb. 19, 1908.]* Feb. 18.
4695. Matthews, Pim, and Strange. Manufacture of white lead. Feb. 25.
4866. Tinkler. Production of colour by heating certain substances. Feb. 27.

COMPLETE SPECIFICATION ACCEPTED.

- 5685 (1908). Davey and Davey. *See under I.*

(B.)—RESINS, VARNISHES.

APPLICATION.

4878. Strange and Burrell. Manufacture of varnish. Feb. 27.

(C.)—INDIA-RUBBER.

APPLICATIONS.

4031. Price. Apparatus for reducing vulcanised rubber or rubber mixtures to powder. [Addition to No. 893 of 1907.] Feb. 18.
4154. Commercial Products Co. (Brend). Production of a plastic and elastic substance.* Feb. 19.

COMPLETE SPECIFICATIONS ACCEPTED.

- 3659 (1908). Immisch. Manufacture of goods of rubber, ebonite, or vulcanite. Feb. 24.
3940 (1909). Immisch. Manufacture of goods of rubber, ebonite, or vulcanite. Feb. 24.

XIV.—TANNING, LEATHER, GLUE, SIZE, Etc.

APPLICATIONS.

4130. Lake (Fiber Products Co.). Production of artificial leather.* Feb. 19.
4488. Lehmann. Treatment of skins and hides to remove fat, grease, and lime, and to disinfect them.* Feb. 23.

XV.—SUGAR, STARCH, GUM, Etc.

APPLICATION.

4263. Woosnam (Whetham). Treatment of amylaceous substances. Feb. 20.

XVII.—BREWING, WINES, SPIRITS, Etc.

APPLICATIONS.

4584. Thompson (Topf und Soehne). Drums for the germination of malt.* Feb. 24.
4604. Vallat. Apparatus for distilling or rectifying wines, brandy, fermented worts, alcohols, petrols, benzines, essential oils, and other liquids. [Fr. Appl., Feb. 25, 1908.]* Feb. 24.
4635. Adlam. Apparatus for chilling and carbonating beer, stout, and other liquids.* Feb. 25.

XVIII.—FOODS; SANITATION, WATER PURIFICATION; AND DISINFECTANTS.

(A.)—FOODS.

APPLICATION.

4210. Little. Treatment of flour. Feb. 20.

COMPLETE SPECIFICATION ACCEPTED.

- 27,218 (1908). Wesener. Apparatus for preparing gaseous mixtures for bleaching flour, etc. Feb. 24.

(B.)—SANITATION; WATER PURIFICATION.

APPLICATION.

4212. Candy. Purification of water. Feb. 20.

XIX.—PAPER, PASTEBOARD, Etc.

APPLICATION.

3883. Armitage and Ibbetson, Ltd., and others. Glazing paper, cardboard, etc.* Feb. 17.

COMPLETE SPECIFICATIONS ACCEPTED.

- 4390 (1908). Stevens. Celluloid and process for making same. March 3.
8268 (1908). Cross and Russell. Treatment of by-products from esparto grass. March 3.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENTIAL OILS, AND EXTRACTS.

APPLICATIONS.

4128. Imray (Meister, Lucius, und Brüning). Manufacture of 1-p-dialkylaminoaryl-2,4-dialkyl-3-oxy-methyl-5-pyrazolones. Feb. 19.
4246. Imray (Meister, Lucius, und Brüning). Manufacture of arsonoaryl glycolic acids and arsonoarylthioglycolic acids. [Addition to No. 9855 of 1908.] Feb. 20.
4321. Newton (Bayer und Co.). Manufacture of a pharmaceutical compound. Feb. 22.
4564. Zimmermann (Chem. Fabr. auf Actien, vorm. E. Schering). Manufacture of albumose silver compounds. Feb. 24.
4604. Vallat. *See under XVII.*

COMPLETE SPECIFICATIONS ACCEPTED.

- 11,457 (1908). Johnson (Boehringer und Soehne). Manufacture of salicylic acid derivatives. Feb. 24.
15,122 (1908). Johnson (Verein. Chininfabr. Zimmer und Co.). Santalol esters. Feb. 24.
21,566 (1908). Baekeland. Condensation product. Feb. 24.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

APPLICATION.

4713. Fenske. Manufacture of irregular grain screen plates for direct colour photography. Feb. 25.

COMPLETE SPECIFICATION ACCEPTED.

- 12,341 (1908). Smith. Toning reagents and processes for toning photographic prints. Feb. 24.

XXII.—EXPLOSIVES, MATCHES, Etc.

APPLICATIONS.

3937. Lake (Verein. Köln-Rottweiler Pulverfabr.). Manufacture of plastic ammoniacal saltpetre explosives.* Feb. 17.
4094. Guttman. Buildings for the manufacture and storage of explosives. Feb. 19.

XXIII.—GENERAL ANALYTICAL CHEMISTRY.

APPLICATION.

3733. Davies and McLellan. Determining the condition of the atmosphere in schools, factories, etc. Feb. 15.

COMPLETE SPECIFICATION ACCEPTED.

Honorary Treasurer:

Thomas Tyrer, Stirling Chemical Works, Stratford, E.

Honorary Foreign Secretary:

Dr. Ludwig Mond, F.R.S.

General Secretary: Charles G. Cresswell, 59, Palace Chambers, Westminster, S.W.

Telegraphic Address: 59, Palatable, London.

Telephone Number: 715 Victoria.

ANNUAL GENERAL MEETING.

NOTICE IS HEREBY GIVEN that the Annual General Meeting of the Society will be held in the Jehangier Hall, Imperial Institute Buildings, London, S.W., at 10.30 in the morning of Wednesday, May 26th next.

In accordance with the provisions of By-law 21, notice is hereby given that those members whose names are printed in *italics* in the list of Council will retire on their respective offices at the forthcoming Annual Meeting.

Prof. Ira Remsen has been nominated to the office of President under By-law 20; Dr. G. Beilby, F.R.S., Mr. Grant Hooper, and Dr. R. Messel, have been nominated as Vice-Presidents under By-law 21, and Prof. R. Meldola has been nominated a Vice-President under By-law 20. Mr. Thomas Tyrer has been appointed Hon. Treasurer, and Dr. L. Mond, F.R.S., Hon. Foreign Secretary, under By-law 35.

Members are hereby invited to nominate, on or before April 22nd next, fit and proper persons to fill four vacancies among the ordinary members of the Council under By-law 24. Forms for this purpose can be obtained, on application, from the Secretary of the Society.

By-law 23:—An ordinary member of Council shall be nominated by ten or more members upon Form B in

the Schedule, a copy of which form shall be furnished by the Secretary upon the written or verbal request of any member, but a member shall not be eligible to sign more than one such nomination form, and the member nominated shall sign the declaration set forth on the form. A nomination shall be declared invalid by the Council if:

a. The member thereon nominated is disqualified for election, or ineligible to be elected, as provided by the By-laws.

b. The nomination is not made on the authorised printed form or substantially not in the manner directed thereon.

c. The nomination form is signed by less than ten members not disqualified or not ineligible to nominate as provided by the By-laws.

d. The nomination form is not received before or upon the day appointed therefor.

e. The member nominated has not signed the declaration printed upon the form.

A member whose nomination aforesaid is declared to be invalid shall receive notice thereof from the Secretary, and shall not be submitted for election.

Notice is also given under the provisions of By-law 38 that the Regulations set forth below will be submitted for consideration and confirmation by the members assembled at the same meeting.

CHARLES G. CRESSWELL.

Secretary.

DRAFT REGULATIONS

TO BE SUBMITTED TO

THE ANNUAL GENERAL MEETING

FOR CONFIRMATION.

(Under By-Law 38.)

MEMBERS.

1. At whatever period of the year a new Member may be elected he shall be required, unless the Council shall determine otherwise, to pay his subscription for that year; having done which he shall be entitled to receive all the numbers of the Society's Journal for that year. (c.f. By-law 7.)

2. If a Member who has been duly elected, and has paid an Entrance Fee and one or more subscriptions, resigns under By-law 14, and later seeks re-election, the Council may re-admit him without further Entrance Fee.

ANNUAL GENERAL MEETING.

3. When a ballot is required under By-law 2, then at such stage in the proceedings of the Annual General Meeting as shall be most convenient, the Members present shall hand their Ballot Lists to the General Secretary, or, in his absence, to such other person as the President may appoint. Members unable to attend the Meeting may send their Ballot Lists before the Meeting to the General Secretary in sealed envelopes. Each such sealed envelope must be marked "BALLOT LIST," and must, moreover, have written upon it the name of the Member sending it. The names written upon such sealed envelope having been compared with the Society's Register by the General Secretary, such sealed envelopes shall be opened at the Meeting by Scrutators appointed by the Meeting. The Scrutators shall see that the conditions of the Ballot are strictly fulfilled. Any Member shall be at liberty to strike out any name or names of Ordinary Members of Council printed on his voting paper.

COMMITTEES.

4. No Special Committee, nor any Committee of a Local Section shall have any control over the funds of the Society, except to the extent to which funds for its use may be voted by the Council. An account of the manner in which any funds so voted for the use of any Committee have been expended shall be furnished to the Council on or before the 15th of November in each year.

LOCAL SECTIONS.

5. All elections to the Committee of a Local Section and all elections of Officers of the Section, with the exception of those to fill up unforeseen vacancies, shall take place so that they can be reported to the Council in time to be considered at the Meeting held under By-law 24 not less than two months prior to the Annual General Meeting; but the Members of Committee and Officers thus elected shall not take office and those whom they are to succeed shall not retire from office until the close of the Annual General Meeting afore-said.

CHARLES G. CRESSWELL,
Secretary.

Birmingham Section.

Meeting held at Birmingham on Thursday, February 4th, 1909.

MR. HARRY SILVESTER, B.Sc., F.L.C., IN THE CHAIR.

THE INFLUENCE OF SMALL QUANTITIES OF ELEMENTS IN COPPER ON ITS REACTIONS WITH NITRIC ACID.

BY J. H. STANSBIE, B.Sc. (LOND.), F.L.C.

The investigation set forth in this paper is a continuation of that already described (this J., 1906, 45, 1071; 1908, 365). It deals particularly with the influence of small quantities of arsenic, phosphorus, and lead on the reactions of alloys of these elements with copper when the alloys are dissolved in nitric acid of sp. gr. 1.2, the reactions taking place at a temperature of 65° C. It also deals with alloys of lead and copper, and with the influence of variations in the temperature of the reaction and the concentration of the acid solution.

It is claimed that the first experiments prove conclusively that the presence of arsenic in small quantities has marked effects upon the reactions of copper with nitric acid, and that these effects are not cumulative, but increase to a maximum as the percentage of arsenic increases, and then decrease with further increase in the amount of arsenic. In former experiments the volume of nitric oxide liberated was taken as an indication of variations in the reactions, but these experiments, which were made with the apparatus already described, were found not to give sufficient information of the general reactions, and the apparatus was modified. With this new form of apparatus other quantities may be determined, and more certain evidence of the reactions obtained.

The alloys were prepared with every precaution to ensure the required composition. Alloys which did not fulfil the weight conditions were rejected. The compositions given in the tables are as prepared, and analyses were made in several cases to confirm the general results.

The nitric acid was distilled twice from a Wurtz flask, the first portions coming over in each case being rejected. The purified acid was then bleached by passing a current of pure, dry, and dust-free air through it while maintained at a temperature of 60° C. It had a sp. gr. of 1.417, and was diluted with re-distilled water to sp. gr. 1.2. The acid was found to be free from sulphate and chloride, and 50 c.c. evaporated in a platinum dish left only a slight stain on the dish. Griess's test gave 0.2 mgrm. of nitrous acid in 50 c.c.

The experiments with the alloys were made under exactly the same conditions, the only variable being the composition of the metal itself. The apparatus is described in a previous paper (this J., 1908, 365).

With regard to the accuracy of the apparatus it may be said that gas volumes can be measured easily to within 0.5 c.c., and the volume collected was usually upwards of 200 c.c. With careful measurement of the acid solution it is estimated that the error would be less than 10 mgrs. of acid. Every precaution was taken to bring the reaction beaker to the same position on the bung for each experiment, so as to keep the internal volume of the apparatus as constant as possible.

From the researches of Dixon, Raschig, Mandl and Russ, and others, it is clear that the conversion of nitric oxide into nitric peroxide by admixture with oxygen is not so simple as is usually stated. A portion of the nitric oxide passes through the trioxide stage, and if any of this is dissolved before further oxidation takes place, the volume of oxygen required to remove nitric oxide from a mixture of gases containing it is reduced by this amount. It may be observed, however, that if the oxygen is added with sufficient rapidity, and in considerable excess, the error introduced is negligible in a comparative series of experiments.

The solutions in the measuring flasks are made up to the mark, and the carbonate solution allowed to stand for two days for the whole of the basic copper carbonate to separate out. Generally the solution was quite free from copper; but in a few cases traces of the metal were found to be present, and the solution required boiling to complete the precipitation. Both solutions are titrated with standard permanganate and ammonium ferrous sulphate, for nitrous acid, and with standard nitric acid for excess of the alkalis, using methyl orange as an indicator.

Nitric peroxide is a constituent of the gaseous mixture liberated from the acid solution under the conditions observed, and is absorbed by the solution of sodium hydroxide in the absorption tube.

The weight of the nitrous acid found in the hydroxide solution, compared with the weight of the alkali neutralised, is always such as to show conclusively that part of it is formed from the nitric oxide with which the nitric peroxide is mixed when it enters the tube for absorption. This is in accordance with the statement made by Divers (J.C.S., 1899, 86), that the red gas obtained by the action of arsenious oxide on nitric acid of sp. gr. 1.35 is absorbed by sodium hydroxide with formation of pure sodium nitrite. The greater part of this gas is known to be a mixture of nitric oxide and nitric peroxide.

According to Dixon and Peterkin (J.C.S., 1899, 614), there is evidence that nitrogen trioxide is formed in small quantity when nitric peroxide and nitric oxide are mixed together, and as this is removed by absorption in the alkaline solution the equilibrium would be disturbed, and more of the trioxide would form, so that the whole mixture would react as the trioxide.

There is always a slight excess of alkali neutralised over nitrous acid found in the hydroxide solution, and as this varies in the different experiments it is most probably accounted for by traces of acid carried over from the beaker by the escaping gases. Nitric acid is evidently not formed in the reaction, and the results of the whole series of experiments make it clear that the reaction in the hydroxide solution is expressed by the equation:

It is, therefore, assumed that equal volumes of nitric peroxide and nitric oxide are absorbed, so that the volumes of the absorbed gases can be calculated. The volume of absorbed nitric oxide is added to the volume collected in the cylinder, and determined by the addition of oxygen.

From the gas collected in the cylinder, and the nitrous acid found in the hydroxide solution, the following quantities are determined and calculated. Total volume of nitric oxide liberated: volume of nitric peroxide liberated: weight of nitrous acid formed, and weight of nitric acid equivalent to the alkali neutralised.

The presence of the nitrous acid in the main solution is probably due to several reactions. It is well known that nitrous acid in aqueous solution is decomposed with evolution of nitric oxide, and formation of nitric acid, when the solution is heated. But according to Veley (Proc. Roy. Soc., 1892, 52-27) the action is reversible in the presence of free nitric acid. Thus:—

and the condition of equilibrium is reached when the ratio of the molecules of nitric acid to those of nitrous acid is 9 : 1. Either this ratio is a function of the temperature of the solution, or the presence of copper nitrate and nitrite modifies the reaction, for in the case of the dis solution of pure copper, at 65° C., during which nitric oxide is liberated freely, it is 17 : 1. Thus the re-solution

of any nitric oxide, formed by direct reduction of nitric acid, would proceed until the equilibrium point was reached, and then the remainder of the gas would escape entirely from the solution.

The formation of nitrous acid by direct reduction of nitric acid would influence the dissolution of nitric oxide by the solution in which it was liberated, as equilibrium would be the sooner reached. Also, it would seem that the total quantity of nitrous acid present in the solution of a metal depends partly upon the stability of the nitrite of the metal itself. This view is supported by the results obtained with other metals. The marked difference in the weights of nitrous acid in the solutions of copper and silver respectively is probably due to the greater stability, of the silver nitrite.

The liberation of nitric peroxide indicates another source of nitrous acid in the solution, as part of this compound would react with nitric oxide in the presence of water to reform the acid and thus pass back into solution. It would therefore appear that any quantitative determination of the different reactions by which the whole of the nitrous acid is formed in the main solution would prove a difficult problem.

The weight of nitrous acid, and the weight of nitric acid equivalent to the sodium carbonate neutralised, are determined in the main solution. The former is given in the tables, the latter is added to the quantities calculated from the hydroxide neutralised, and the nitric oxide and nitrogen liberated. The sum of these weights is given in the tables as acid traced.

The weight of nitric acid used up in the secondary reactions is also given in the tables.

Weight of nitric acid required for 250 c.c.
of the solution = 0.0393 gram.

Nessler's test.

Weight of ammonia in 500 c.c. of the
sodium carbonate solution = 0.2 mgm.

It is generally stated that ammonia is not formed in the reactions of copper with nitric acid, and that sodium carbonate free from ammonia is difficult to obtain. The carbonate used in the experiments was prepared from the bicarbonate, and heated in a muffle for an hour at a red heat. In a blank experiment made with it only a trace of ammonia was detected.

The sodium hydroxide solution gave only a trace of ammonia. The analysis of the residual gas gave no indication of the presence of nitrous oxide in it. This was also found to be the case with the residual gas from the dissolution of copper-arsenic and copper-phosphorus alloys. It is clear then that nitrous oxide is not one of the products of the secondary reactions under the conditions of the experiment; or if any of this gas is formed it is dissolved by the water in the collecting cylinder.

The quantities derived from the data given above are stated in Table I, line 3.

The weight of nitric acid used up in the secondary reactions is calculated from the relations:

$$\frac{\text{HNO}_3}{\text{NO}}; \frac{\text{HNO}_3}{\text{N}}; \frac{\text{HNO}_3}{\text{HNO}_2}; \frac{\text{HNO}_3}{\text{NH}_3}; \frac{2\text{HNO}_3}{\text{N}_2\text{O}}$$

and is regarded as an important quantity in the investigation.

The influence of variations in temperature.

A number of experiments were made to determine the influence of variations in the temperature at which the reaction takes place, all the other conditions being kept as constant as possible. The data given in the table (I.) show that the distribution of the products of the secondary reactions and the quantity of acid used up in these reactions may be appreciably modified by even small variations in temperature. This presents the one difficulty in obtaining perfectly uniform results, as it is not easy to confine the reactions within a very small range. The range within which the experiments were worked did not in the great majority of cases exceed two or three degrees, and apparent anomalies are to be explained by undetected variations. It is then to be understood that the temperatures given in the tables represent small ranges.

Inspection of columns 5 and 6 in Table I. shows that practically the whole of the acid used was traced, so that no notable reaction escaped observation; and it may be remarked that the solubility of nitrogen and nitric oxide in the water over which the gaseous mixture is collected must be very small, as it seems to have very little influence on the general results. This is in accordance with the conclusions of A. Christoff (*Zeits. Phys. Chem.* 1906, 622), who has shown that there is no measurable absorption of such gases as hydrogen, oxygen, and nitrogen through a water surface in 20 minutes. The same is probably true for nitric oxide, the principal gas dealt with in this investigation. The secondary reactions are evidently of the same character, but vary quantitatively, and the effect on the distribution is also very marked. Columns 8 and 13 show the effect of variations in temperature on the nitrous acid in solution, and indicate that part at least of the nitric oxide is formed from it. Column 16 shows that the quantity of acid used up in secondary reactions decreases with an increase in temperature.

The influence of concentration of acid.

The influence of variations in the concentration of the acid solution is just as marked as that of variations in temperature. This will be seen by reference to Table II. The weight of the acid in solution varied somewhat, but not sufficiently to exert any marked influence on the

EXPERIMENTS WITH PURE COPPER.

The results obtained from the dissolution of 1 gram of copper in 15 c.c. of 1.2 nitric acid containing 5.883 grams of HNO_3 , at 65° C., are given below.

The dissolution of the metal.

Volume of gas collected in cylinder ..	= 229.5 c.c.
Volume of oxygen added	= 150 "
Volume of residual gas	= 125.5 "
Volume of hydrogen in apparatus at commencement	= 45 "
Temperature and pressure = 15° C. and 749 mm.	

Analysis of residual gas.

20.8 c.c. of the gas mixed with excess of hydrogen gave on explosion a contraction of 30.6 c.c.	= 10.2 c.c. of oxygen.
Calculated volume of oxygen present in 20.8 c.c. of gas	= 10.5 c.c.
48.3 c.c. of the gas gave on explosion a contraction	= 17.5 " of hydrogen.
Calculated volume of hydrogen present	= 17.7 c.c.

Titration with standard permanganate.

Volume of permanganate required for 50 c.c. of the sodium carbonate solution	= 13.56 c.c.
Weight of nitrous acid in 500 c.c. of the solution	= 0.1356 gram.
Volume of permanganate required for 50 c.c. of the sodium hydroxide solution	= 5.68 c.c.
Weight of nitrous acid in 250 c.c. of the solution	= 0.0284 gram.

Titration with standard acid.

Volume of acid required for 50 c.c. of the sodium carbonate solution	= 15.33 c.c.
Weight of sodium carbonate in excess in 500 c.c. of the solution	= 1.533 gram.
Difference in volume of acid required for 25 c.c. of the sodium hydroxide solution before and after use	= 0.33 c.c.

reactions. It was found difficult to control the temperature in the case of the 1.3 acid, as the action proceeded very rapidly.

It is evident that with acid above 1.2 specific gravity the formation of nitric peroxide becomes very marked, and the smaller quantity of nitrous acid in solution seems to indicate its source, although it may be the product of a purely secondary reaction in the more concentrated acid. Also, the acid used up in secondary reactions increases notably when the concentration is above 1.2.

The dissolution in the 1.1 acid was very slow, requiring 90 minutes for completion; while in the 1.3 acid it was complete in 5 minutes. The 1.2 acid was found to give a steady action which is complete in about eight minutes, seldom varying by more than a few seconds in the various experiments. For this reason it was selected for the general experiments.

Alloys of copper and arsenic.

Table III. contains the results of a series of experiments with copper arsenic alloys dissolved in nitric acid of sp. gr. 1.2 at a temperature of 65° C. One gram of the alloy and 15 c.c. of the acid solution were used in each case.

It may be remarked that while the results given in this table confirm the earlier ones, they also considerably extend the scope of the observations. The most notable effects of variations in the composition of the alloys on their reactions, are the decrease in the volume of gas liberated, and in the quantity of acid used up in the secondary reactions, to a minimum as the percentage of arsenic increases, and then an increase in these quantities with a further increase in the content of arsenic. The variations in the volume of nitric oxide and nitrogen are also very marked. The first passes through a minimum and the second through a maximum as the arsenic increases. These important quantities are traced in Fig. 1.

Fig. 1.

The numbers given in columns 8, 12, and 16 of Table III. are plotted on the curves A, B and C respectively.

Alloys of copper and phosphorus.

In Table IV. the results of experiments with a series of copper-phosphorus alloys are given. One gram of each alloy was dissolved in 15 c.c. of 1.2 acid, at 65° C.

The results above are of the same general character as those given in Table III., but the maximum effect is produced by a smaller content of phosphorus, and is not so marked as in the copper arsenic series. The maximum effect of phosphorus on the chemical relations of copper appears to be produced by a content of phosphorus in the neighbourhood of 0.025 per cent. (See Fig. 2.)

It may be noted that the quantities of phosphorus, arsenic, antimony, and bismuth which produce the maximum effect are in the order of their atomic weights, and it may be that the atomic volume of the added element is a factor in the influence it exerts upon the copper.

Fig. 2.

The numbers in columns 8, 12, and 16 of Table IV. are plotted on the curves A, B and C respectively.

Alloys of copper and lead.

It has been shown that small quantities of bismuth exert little or no influence on the chemical relations of copper and nitric acid, and it was thought that lead, which by itself produces a different set of reactions with nitric acid, might yield further information. It is well known that nitrous oxide is an important product of the secondary reactions of lead with nitric acid; but in the experiments with copper-lead alloys, the examination of the residual gas after the removal of the nitric oxide gave no indication of nitrous oxide even with an alloy containing 60 per cent. lead. The copper, when present in considerable quantity, appears to entirely suppress the formation of nitrous oxide. The analysis of the residual gas was made, as already indicated, by explosion with excess of hydrogen. As the excess of oxygen in the residue is known, the nitrous oxide is easily determined when present.

The following are the results obtained with the gas from the dissolution of (a) the copper-lead alloy containing 60 per cent. lead and (b) pure lead.

Analysis of residual gas.

(a) Volume of residual gas taken	=32.6 c.c.
Volume with hydrogen added	=80.8 "
Volume after explosion	=37.0 "
Volume of oxygen known to be present ..	=14.7 "
Then $80.8 - 37 = 43.8$; and $14.7 \times 3 = 44.1$.	

The contraction therefore is entirely due to oxygen present.

(b) Volume of residual gas taken	= 32.0 c.c.
Volume with hydrogen added	= 90.0 ..
Volume after explosion	= 44.6 ..
Volume of oxygen known to be present ..	= 12.2 ..

Then $90 - 44.6 = 45.4$; and $12.2 \times 3 = 36.6$.

Therefore $45.4 - 36.6 = 8.8 =$ volume of nitrous oxide present in 32 c.c. of the gas, as no contraction in volume takes place when nitrous oxide is reduced to nitrogen. The excess contraction is therefore due to the removal of a volume of hydrogen equal to that of the nitrous oxide reduced.

The experiments made with the copper-lead alloys are divided into two sets. In the first set alloys containing from 0.05 to 5 per cent. of lead are dealt with, and in the second, alloys with 20 per cent. and upwards. The results are given in Tables V. and VI., and from the quantities in columns 8, 10, and 16 of Table V. it is seen that small percentages of lead exert little or no influence on the reactions of copper with the acid, so that lead acts similarly to bismuth in this respect. The decrease in these quantities for the alloys containing an appreciable amount of lead is evidently due simply to the presence of the metal. One gram was taken in each case, and the other conditions kept as constant as possible.

In the second set (Table VI.), the weight of alloy taken is such that the same weight of acid is used in the conversion of the metals into nitrates. This allows of a better comparison of results, as it eliminates the effects of variable concentration. If then the temperature is kept constant, the only variable is the composition of the alloys, and differences in the reactions can be the more readily detected. These conditions appear to be necessary if the results are to be strictly comparable, for the escape of gaseous products from the solution depends upon its concentration and temperature, and anything that disturbs this relation, or the relation between the solution and the gas above it must cause a variation in, and a re-distribution of, the components of the system.

Examination of Table VI. shows that the secondary reactions of copper-lead alloys are very much the same as those of copper, although the reactions of lead itself are very different. There is an apparently simple explanation of this, for it is noticed that directly the alloy commences to dissolve and copper nitrate to appear in the solution the metallic particles turn red, showing that copper is deposited as fast as it is dissolved by the acid. The process is therefore practically the same as the dissolution of the copper in nitric acid, and the dissolution of lead in copper nitrate: no doubt with a more dilute solution and a slower action this would be strictly true. As the dissolution of lead by copper nitrate is the result of exchange between the two metals, no gaseous products result, and any disturbing effect would be due only to the accumulation of lead nitrate in the solution. Another point to be noticed is the support given to the statement that part at least of the nitric oxide liberated from the solution is a product of the decomposition of nitrous acid present or formed in it. By comparing the quantities in columns 8 and 13, Table VI., for the 60 and 80 per cent. alloy it is seen that the larger volume of nitric oxide corresponds to the smaller weight of nitrous acid.

On referring to column 7 it is seen that the difference between acid used and acid traced is very marked when nitrous oxide forms a considerable proportion of the evolved gas. This is no doubt due largely to the solubility of the nitrous oxide.

The reactions with lead, and with lead containing 0.1 per cent. of copper, show that a small percentage of copper in lead has little or no influence upon the reactions of lead itself with nitric acid.

According to Freer and Higley (Roscoe and Schorlemmer's Chemistry, Vol. I., p. 531), the liberated gas from the dissolution of lead in nitric acid of sp. gr. 1.2, contains 40 per cent. of nitrous oxide. This differs from the result (55 per cent.) given in Table VI., but as the temperature of the reaction is not given by them, the difference in the percentages of the gas is probably due to the different temperatures used.

The general character of the reactions of copper-lead alloys agrees with the observations of Acworth and Armstrong, that brass gives similar reactions to copper when it is dissolved in nitric acid, and it is probable that the explanation is the same.

SUMMARY.

At the conclusion of the first set of experiments, the opinion was expressed that the chief cause of the decrease in the volume of nitric oxide liberated by the dissolution of copper alloys in nitric acid is the formation of a solid solution of the added element, or of a compound of that element, in the excess of copper. Further investigations have served to confirm this view. There is very little doubt as to the formation of solid solutions in alloys of copper with arsenic, antimony, and phosphorus, and further that they become saturated within the limits indicated by the nitric acid reactions. When the saturation point is passed, the element or compound in solution is rejected on solidification, and in this rejection, not only does the excess segregate, but the solution swings past its saturation point, and becomes undersaturated. The concentration of the solid solution is thus reduced, and the influence of the dissolved element is lessened. It must, therefore, pass through a maximum as the percentage of the added element increases. The experiments with copper-bismuth alloys support this view, for the bismuth seems to be entirely rejected by molten copper on solidification, and no solid solution is formed. The experiments with the copper-lead alloys were undertaken, because these alloys have been investigated pyrometrically by Heycock and Neville (Phil. Trans. 189a, p. 42). They state that a solid solution of lead in copper does not exist with small percentages of lead. They also find that a eutectic mixture is formed in lead containing about 0.06 per cent. of copper. Reference to Table V. will make it clear that the influence of lead in small quantities on the reactions of copper with nitric acid is practically that of a simple mixture of the two metals. The great similarity of the reactions of pure lead and lead containing 0.1 per cent. of copper, indicates that the formation of a eutectic alloy containing a small percentage of the added element exerts little or no influence on the reactions of the metal, and this seems to be a natural interpretation, as the eutectic alloy is simply a mixture of the two metals.

The opinion may be expressed that the purely chemical investigation of the reactions of nitric acid with alloys should form a valuable aid to the microscopic and pyrometric examination of these important bodies, that is now being carried on with such far-reaching results. It is evident that the primary reactions alone are of a comparatively simple character, although they may furnish valuable information with regard to the heat of combination as shown by Drs. Baker and Galt, in their independent investigations of the effect of dissolving copper zinc alloys in chlorine and bromine solutions. But the secondary changes taking place in nitric acid solutions seem to be able to furnish information as to the relations of the metals in an alloy to each other. The subject is admittedly a complicated one, but if the acid is pure and the temperature of the reaction is carefully regulated, there is no reason why this method should not form a valuable aid in researches on alloys.

In the comparison of results obtained with pure metals it seems to be a necessary condition that the weights of the metals taken should be arranged so that the same weight of acid is used up in the primary reactions. This leaves the acid solution in which the secondary reactions take place of the same concentration. The same principle holds good for alloys in which notable proportions of the second metal are present. The weight of acid used up in the secondary changes is an important quantity in the investigation of a series of alloys.

Some metals react with their own nitrates in solution, but this does not appear to exert much influence in investigations in which excess of acid is used and the whole of the metal dissolved. For during the first part of the reaction when the metal is in excess the concentration of the nitrate in the solution is low, and at any time it could but slightly assist in the secondary changes under the conditions observed in the experiments.

The absence of nitrous oxide from the gases liberated by the dissolution of alloys of copper and lead up to 60 per cent. lead is remarkable. According to Heycock and Neville such alloys when very slowly solidified from the molten state consist of two conjugate alloys completely separated from each other in layers. When quickly solidified they form a kind of emulsion of two immiscible alloys.

The suppression of the nitrous oxide which is the characteristic gas in the lead reaction indicates a somewhat close relation between the two metals, for the reactions of the alloy are different to those of a mere mixture of the two metals. The copper appears to dominate the secondary reactions until the proportion of lead present is very large.

The protective action of one metal over another in a nitric acid solution is well shown in the case of gold-silver alloys from which the silver is not freely and completely dissolved until it forms upwards of 70 per cent. of the alloy. It may be that some such action takes place during the dissolution of lead in copper-lead alloys, although the copper itself dissolves. There is, however, the other explanation, which may be sufficient to account for the absence of nitrous oxide, and that is, the dissolution of lead in copper nitrate with precipitation of copper. In that case the change would be equivalent to the dissolution of alloy in the acid, and it is noticed that the particles of alloy in the acid are distinctly red until they finally disappear, showing that copper is constantly deposited upon them, and as constantly redissolved by the nitric acid.

It is well known that the physical and mechanical properties of metals and alloys are considerably modified by the presence of small quantities of added elements, and this is of considerable practical importance when the influence is in the direction of improving these properties, or in modifying one or more of them. The general effect of arsenic on copper is well known, but there is no general consensus of opinion among practical men as to the best proportion of arsenic to give the required effect. If, as is probably the case, the proportion which produces the greatest modification in the chemical relations of the alloy, acts in the same direction with regard to its physical properties, information of practical value is furnished by investigating the chemical properties of the useful metals and alloys.

Summary of views concerning the reactions of nitric acid with metals.

Very little quantitative work in connection with the gaseous products of the reactions of nitric acid with metals appears to have been done previously to 1870, although the general character of the changes had been well studied in the case of a few metals. The views generally entertained were in accordance with the hypothesis that in the formation of a salt by the interaction of an acid and a metal, the oxide of the metal is first formed and then reacts with the acid. This idea had its origin in the application of the Phlogistic Hypothesis to the explanation of salt formation. The metal was supposed to undergo calcination in the acid, and the resulting salt to dissolve in the acid solution. To account for the products of the dissolution of a metal in nitric acid it was supposed that the acid itself was the direct cause of the oxidation, and the gaseous products were the result of this primary reaction.

Thenard (*Traité de Chimie*, 1834, p. 362) sets forth this view, and describes the dissolution of copper in nitric acid with liberation of nitric oxide. He recommends the use of diluted acid, and regulation of the temperature. With the strong acid the action is rapid, much heat is evolved, and the nitric oxide is mixed with nitrous oxide and nitrogen.

Gmelin (*Chemistry*, English translation, Vol. II., 1849, p. 397) states that most metals are oxidised by nitric acid, and the resulting oxides combine with the undecomposed acid to form salts. The gaseous products are derived from the portion of the acid that oxidises the metal, and may consist of hyponitric acid, nitric oxide, nitrous oxide, and nitrogen. If the metal decomposes water, the hydrogen liberated combines with the

nitrogen of the acid, and ammonia is formed. Which of the above products are obtained depends partly on the affinity of the metal for oxygen, and partly upon the temperature and concentration of the acid solution.

Regnault (*Cours Élémentaire de Chimie*, 1851, Vol. I., p. 142) states that nitric oxide or nitrous oxide is liberated according to the nature of the metal. While zinc liberates a mixture of the two gases, copper or mercury gives pure nitric oxide if the acid is sufficiently dilute and the temperature is prevented from rising.

Pelouze and Fremy (*Traité de Chimie*, 1860, Vol. I., p. 351) give a more detailed account of the reactions of metals and nitric acid. The reactions for copper and silver are given, and it is stated that the acid must be dilute or the gas will not be pure. The effects of concentration and temperature are noted, and the appearance of red vapour in the nitric oxide when concentrated acid is used is indicated. The formation of ammonia with tin and its non-formation with copper, silver, and mercury are mentioned. The easily oxidisable metals are said to form ammonia. They also state that if the acid is cooled to -16°C . it has no action on copper. The experiments of Gay-Lussac by which he showed that with very dilute nitric acid containing nitrous acid the quantity of copper dissolved is proportional to the quantity of nitrous acid present, are mentioned, and the inference drawn that the nitric acid exerts no action on the metal. The action of "nascent" hydrogen in the formation of ammonia is referred to.

Brande and Taylor (1863) state that ammonia is formed and ammonium nitrate detected among the products when nitric acid acts upon those metals that decompose water, and refer to the reactions of copper, silver, mercury, etc. They also state that copper, tin and silver are without action on the concentrated acid, but act rapidly on the addition of a little water.

Fownes (1868) referring to copper, states that the reaction is a simple deoxidation of some of the acid by the copper, by which the metal is oxidised; and the oxide so formed is dissolved in the unchanged acid.

The oxidation of the metal by the acid with liberation of gaseous products, and the formation of the salt by the dissolution of the oxide in the excess of acid may be described as the first connected theory of the action of nitric acid and metals. This view was held by Mendeleeff as late as 1891 (*Principles of Chemistry*, Vol. I., p. 71, 1891, Eng. Trans.)

The change in view concerning the nature of acids, and their recognition as salts of hydrogen did away with the necessity of assuming the formation of the metallic oxide as the primary reaction. The simple deduction from the reaction of metals with other acids, is that the primary reaction with nitric acid consists in the formation of the nitrate of the metal with liberation of hydrogen; but as free hydrogen had not been detected in the evolved gases it was supposed that the secondary products were the result of reaction between the "nascent" hydrogen and the excess of acid. This may be called the "nascent" hydrogen theory, and is clearly expressed in Miller's *Chemistry*, Vol. II., p. 154, 1874. It was adopted by Aeworth and Armstrong (*J.C.S.*, 1877, 2, 54) in interpreting the results of their extensive research on the action of nitric acid and metals.

The work of these chemists with nitric acid may be said to be the first of a really quantitative character as far as the gaseous products of the reactions are concerned. Earlier work appears to have been chiefly concerned with the metallic compounds formed; the other products were only dealt with qualitatively. They, however, experimented with most of the common metals, and found that nitric oxide, nitrous oxide, and nitrogen were usually present in the gaseous products, although considerable variations in the percentage composition, and in the total volume of the liberated gas, were observed. In some cases one or other of the gases was absent from the product. Their statement that hydrogen is not a constituent of the gaseous mixture obtained when metals dissolve in nitric acid is incorrect in some cases. Metals that decompose water below a red heat may liberate hydrogen from nitric acid under certain conditions. This was observed, in the case of magnesium, by Dr. A. J.

Ewart (Nature, Dec. 12th, 1901). This, however, may be regarded as another argument in favour of their theory of the general reactions. They express the view that the variations in the composition and volume of the gas obtained by the action of different metals are probably due to the different energy relations of the various metals and the acid solution into which they dissolve, and they suggest that the "nascent" hydrogen takes on, as it were, the character of the metal that sets it free; so that it acts differently towards the acid which it is its function to reduce. Some such conception as this is necessary if the theory of the action of "nascent" hydrogen is to be upheld, for it is evident that equivalent weights of various metals would liberate the same weight of hydrogen, and this, as it is not generally set free, would have to disappear again in bringing about the various secondary changes. Divers (this J., 1904, p. 1185) points out that the term "nascent" is comparatively meaningless in the sense of the hydrogen itself differing in reducing value according to the metal presented to the acid. He regards the metal and the acid together as constituting either the reducing or the hydrogenising agent. This agrees with Ostwald's view of the reduction of nitric acid by metals. He states that the reducing action of a metal depends upon the concentration of the hydrogen which would be required to precipitate the metal from its salts. The function of the nitric acid used up in the secondary changes is to reduce this concentration by oxidising the liberated hydrogen to water, and thus allowing more of the metal to pass into solution. In the case of a metal which does not liberate hydrogen from acids under ordinary conditions, he assumes an exceedingly small concentration of hydrogen, which is still further reduced by the action of nitric acid, so that the metal gradually passes into solution. According to this it is necessary and sufficient to reduce the concentration of the hydrogen below that at which it would precipitate the metal for the dissolution of the metal to proceed. The fact that at the temperature of the atmosphere magnesium liberates nearly pure hydrogen from the dilute acid, and that as the temperature rises the usual gaseous products appear, seems to support the theory for increase in the temperature must tend to increase the concentration of the gas, and this tendency would be opposed by the oxidising action of the acid, which would itself undergo reduction. But it must not be forgotten that the accumulation of nitrate in the solution may modify the changes, or even completely alter them. Whether this or the rise in the temperature is the principal cause of the variation in the composition of the evolved gas requires further investigation.

The important products, other than the nitrate of the metal, that may be formed, either temporarily or permanently in the solution, have now been determined. They are the metallic nitrite, nitrous acid, hydroxylamine, ammonia, and hyponitrous acid. The recent information concerning the formation and reactions of these bodies is largely due to Divers, Rây, Raschig, and Veley; and it may be used to explain the changes by which the gaseous products resulting from the dissolution of a metal in the acid are set free.

According to Divers, the metals may be divided into two classes: (a) those metals that are inactive with nitric acid, except in the presence of nitrous acid as catalyser, and then are converted into molecular proportions of nitrate and nitrite, with water as the only other product. This is the primary reaction. The metals, silver, mercury, copper, and bismuth, belong to this class; (b) those metals that form the nitrate in the primary reaction, together with nitrous oxide, nitrogen, and ammonia, each at the same time, but independently. Zinc, tin and other metals of a strongly basic character belong to this class. All other products must be the result of secondary changes. This is the most recent theory, and is based upon experimental evidence.

In the case of silver, an example of the first class, the reactions are such that nitric oxide is the principal gaseous product, and its liberation is probably due to the interaction of silver nitrite and nitric acid as a secondary change by which nitrous acid is formed, and accumulates in the solution. Under favourable

conditions of temperature and concentration the nitrous acid decomposes thus: $3\text{HNO}_2 = \text{HNO}_3 + 2\text{NO} + \text{H}_2\text{O}$. The liberation of nitric peroxide, which is the result of the interaction of nitrous and nitric acids, takes place as the concentration of the nitric acid increases, thus: $\text{HNO}_2 + \text{HNO}_3 = \text{H}_2\text{O} + 2\text{NO}_2$.

This statement is in accordance with the author's observations, for the liberation of nitric peroxide increases as the reaction proceeds; and as the nitric acid is being added to the beaker faster than it is used up in the reaction, it accumulates in the solution.

Copper and bismuth give similar reactions, but under certain conditions nitrogen is one of the products of the change, and this indicates a further reduction of nitrous or nitric acid. The simple explanation of this is, that ammonia is formed and reacts with nitrous acid as described by Armstrong, with liberation of nitrogen: $\text{HNO}_2 + \text{NH}_3 = \text{N}_2 + 2\text{H}_2\text{O}$. There is no doubt that ammonia is formed, for some remains in the solution even in the presence of excess of nitrous acid. Also from the recent observations of Rây it is possible that hyponitrous acid may be formed and decomposed with liberation of nitrogen thus: $5\text{HNO} = \text{HNO}_3 + 2\text{H}_2\text{O} + 2\text{N}_2$. There seems to be no reason why these reduction and hydrogenisation changes should not be brought about by the metal and the acid, as they only take place to a limited degree.

In the case of the metals of the second class, of which zinc and lead are members, it would appear that the primary changes are such that the greater part of the products other than the nitrate are derived directly from the acid. But the difficulty of limiting the changes to those of a primary character in the case of metals of this class is seen in the case of lead by the evolution of nitric oxide and nitric peroxide, and in the accumulation of nitrous acid in the solution. The action of the metal on its own nitrate must also be taken into account.

The author has not found that any systematic investigations of the reactions of alloys with nitric acid, or attempts to trace the whole of the acid used in the reactions, have been made; and he thinks that the method of examining both the solution and the gaseous products obtained in a single experiment should furnish valuable information of the general reactions with metals and alloys.

By the usual methods the changes taking place in the acid solution when a given metal is being dissolved, together with the effects of concentration and temperature upon such changes, and the composition of the gaseous products of the reactions are determined by independent experiments. Thus, there appears to be some difficulty in correlating the results of the two sets of observations.

It is clear that a number of factors must be taken into consideration in order to obtain a concise view of the various reactions. These may be stated briefly as follows:—

- (1) The concentration and mass of the acid solution.
- (2) The presence of bodies other than water and nitric acid in the solution.
- (3) The nature and purity of the metal or alloy.
- (4) The temperature at which the reactions take place.
- (5) The accumulation of various products in solution.

Thus, the opinion may be expressed that it would possibly lead to a more exact classification of the metals with regard to their action upon nitric acid if they were subjected to exactly the same conditions, and each experiment made as complete as possible.

Some of the effects of variations in the concentration of the acid solution were noticed by the earlier experimenters; while observations on the influence of mass and depth of solution over the dissolving metal are of more recent date. This influence is most noticeable in the case of a gaseous product liberated either at the surface of the metal or in the solution immediately above it, if it reacts with the excess of acid. Thus it is possible to completely prevent the escape of nitric oxide from a solution of sufficient mass, concentration and depth, but in this case nitrous acid appears in the solution in proportion.

The presence of nitrous acid in nitric acid solutions

appears to exert considerable influence on its reactions, and as it seems impossible to obtain a solution of the higher acid absolutely free from the lower one, its presence must always be taken into account. The addition of a second acid which may act as a fixing agent, as in the formation of hydroxylamine, may be found useful.

That the purity of the metal is of importance is again emphasised by the author's experiments, and it seems that the metal must be pure within the limits of possible purity, or it must be considered as an alloy.

With regard to the effects of temperature, the experiments of Dr. Ewart would, if followed up, probably modify present views; but the author is not aware that Ewart, whose experiments were only roughly quantitative, has continued the work, or that any other experimenter has taken it up. The critical temperatures given are: zinc, 0° to 2°; magnesium, 17° to 19°; and copper, 19° to 21°. Below these temperatures the metals are said to show little or no signs of reaction with the acid, but above them the action commences and increases rapidly as the temperature rises.

The experiments of Acworth (J.C.S., 1875, p. 828) make it clear that the accumulation of copper nitrate, and probably nitrite, in the nitric acid solution which is dissolving copper influences the composition of the

gaseous products. Thus he found that the presence of the nitrate increases the proportions of nitrous oxide and nitrogen in the collected gases, and decreases that of nitric oxide. In this connection it may be remarked that the absence of nitrous oxide from the gas collected in the author's experiments with copper and its alloys is no doubt due to the steady flow of acid into the beaker continually flooding the metal, and thus preventing the nitrate from accumulating above it.

Ray allowed the salts to accumulate in the neighbourhood of the surface of the dissolving metal in the case of mercury; while Veley caused a copper ball to rotate in the acid solutions so as to distribute the salt or salts formed through the surrounding liquid. In view of these experiments it may be suggested that further information would be obtained by electro-depositing a metal on a platinum cathode, and then dissolving it in a nitric acid solution under constant conditions, except that in one set of experiments the cathode remains stationary, and in the other is rotated, during the action.

In conclusion, the author hopes that the work presented in this and former papers may be of use not only practically, but also in the development of the theory of the action of metals and alloys upon nitric acid.

Table III.—Alloys of copper and arsenic.

Table IV.—Alloys of copper and phosphorus.

Table V.—Alloys of copper with 5 per cent. or less of lead.

Table VI.—Alloys of copper with lead.

Column.

1. Temperature in degrees Centigrade.

2. Grams of alloy taken.

3. Percentage of second element.

4. Specific gravity of nitric acid used.

5. Mgrams. of nitric acid used.

Column.

6. Mgrams. of nitric acid traced.

7. Mgrams. of nitric acid missing.

8. C.c. of total nitric oxide liberated.

9. C.c. of nitrous oxide found.

10. C.c. of nitrogen liberated.

11. C.c. of nitric peroxide liberated.

12. C.c. of total gas liberated.

13. Mgrams. of nitrous acid in carbonate solution.

14. Mgrams. of nitrous acid in hydroxide solution, half of it formed from nitric peroxide and half from nitric oxide.

15. Mgrams. of ammonia found.

16. Mgrams. of nitric acid used up in secondary reactions.

Liverpool Section.

Meeting held at University, on Wednesday, December 9th, 1908.

MR. MAX MUSEPRATT IN THE CHAIR.

THE UNIVERSITY TRAINING OF TECHNICAL CHEMISTS.

BY PROFESSOR F. G. DONNAN, M.A., PH.D.

The English chemical manufacturer is such a very much abused individual that there must be a great deal of good in him. He is constantly being compared to his disadvantage with his German brother, the employer of scores of University graduates, and with his American brother who, it is related, goes to the University or technical school in *propria persona* and picks his men out. In short, one of the many things laid at the door of the English manufacturer is that he eyes the University graduate, if not exactly askance, at all events with a certain wariness, and that in this and other ways he makes relatively little use of the Universities of the country. Recently, Professor Kipping, in dealing with the subject in his Presidential address to the Chemical Section of the British Association, has uttered a sort of academic chemist's lament. But what about the English chemical manufacturer himself? Perhaps if he were not a silent man he too could utter a lament. I have no intention, however, of entering into the rights and wrongs of that question here. But one thing is, or ought to be abundantly clear to everybody. On the one hand we have the Universities of Great Britain and Ireland enormously increased of late in numbers and presumably in efficiency, and ready to pour forth a correspondingly increased number of young chemists every year. On the other hand, are the manufacturers and employers of trained chemists prepared to offer positions to these? On the part of the Universities there is experienced a certain sense of isolation, a certain want of direct touch with the outer world of industry, and a very considerable difficulty in finding suitable employment for their graduates. It is clearly a case where there is urgent need for conference. Some 9 or 10 years ago the German chemical manufacturers and University teachers met together and discussed the teaching of chemistry at the Hochschulen, with the result that certain reforms were introduced. This is a good example to follow, and it is all the more easily followed in this and other English-speaking countries, since the meetings of the Local Sections of the Society of Chemical Industry provide us with an almost ideal machinery for this purpose. At these meetings manufacturers, directors of technical laboratories, consulting chemists and University teachers meet, or ought to meet together, and there is not the slightest difficulty in, at all events, initiating useful discussions which might lead to the conferences alluded to above. Plain speaking on both sides will do no harm, and is highly necessary.

My object therefore in making the following remarks is to initiate such a discussion in our Liverpool Section. Although our Birmingham and Manchester colleagues have quite recently discussed the same theme, I do not think a discussion of it here will be superfluous. Indeed, it would be an extremely useful thing if every Local Section could take the matter up, and devote at least an evening to it. We should then have a good opportunity of hearing what many of our leading manufacturers and University teachers have to say on the subject, and from the various views so presented, useful conclusions could be drawn.

The first question which is generally considered in a discussion of this sort, is the following one—Is there any essential distinction between the so-called "pure" science taught at our Universities and the so-called "technical" science investigated and utilised in industry? According

Mr. Swinburne, pure science is merely the crude raw material, which only becomes the refined and finished article after it has passed through the hands of the engineer and technical chemist. In a recent inaugural address,

delivered on October 7th, 1908, to the students of the Imperial College of Science and Technology in London, Dr. Henry T. Bovey, F.R.S., Rector of the College, said, "In the case of pure science the resulting fact is viewed as an instance of a law; in the case of technology the fact itself is the important thing. Therefore the idea of utility seems to be the real key to the difference between the two—which seems to be a difference of aim. If our purpose is to establish a law we call it pure science; if our purpose is to establish a fact we call it applied science or technology." Mr. Swinburne's definition is certainly amusing, whilst that of Dr. Bovey is interesting from a philosophical standpoint. No doubt both contain a great deal of truth. I think, however, for the practical purpose of our present enquiry, the matter stands as follows. The orderly, arranged facts and the resulting laws and principles of chemistry constitute the science of chemistry. This science is obviously the same whether chemical reactions take place in a University laboratory or in a works plant. But in a works the science of chemistry is combined with two other great sciences, namely, the science of economical production and that of engineering. It is clear that the technical chemist, whilst knowing all about the facts and principles of chemistry, has two new variables to deal with, namely price or commercial possibility, and bulk or engineering possibility. As our American friends well express it, he has to reckon with the dollar co-ordinate, and also, as I have just said, with the engineering or "bulk" co-ordinate. If we say that the University Laboratory usually deals with only one co-ordinate or variable, *i.e.*, that of scientific truth or accuracy, then the works laboratory deals with a higher space determined by the three co-ordinates of scientific accuracy, price and bulk. The success of a research in a University laboratory is determined by the truth of the fact or principle established, whilst the success of a technical operation or research requires in addition the correct determination of the two other factors already mentioned.

These considerations will, I think, bring us right into the middle of our subject at once. It is clear that the first and paramount duty of the University chemical department is to teach the future technical chemists the principles and some of the facts of chemical science. I wish to lay particular emphasis on the necessity of giving the technical chemist a thorough-going grasp of theoretical principles. When the young chemist enters the works, what has he to offer his elder and more experienced colleagues, but perhaps a fresher knowledge of chemical theory and principles? As regard economics, knowledge of special facts, knowledge of practical chemical analysis and chemical engineering, he is almost sure to have nearly everything to learn. He should enter the works with his head full of theory and his soul full of humility. He has only three or four years at the University to learn the principles of his science, the principles which inflexibly govern all chemical operations. Afterwards he may have two score years and ten to learn the stern necessities and conditions of chemical industry and technical practice. The University must set him thinking, so that he will go on thinking (and theorising) amidst the rush and stress, the failures and rebuffs of modern industrial conditions.

As Professor Ostwald has told us, good practice is founded on good theory, and when a man's theory doesn't lead to good practice, it is because his particular theory is a bad or an insufficient one, not because he has a theory. In other words, good theory means a sound and comprehensive grip of chemical principles. Without that possession, a man placed in new conditions will not be able to think effectively. He will be like a ship without a compass on a strange and stormy ocean. I think I may say without impertinence that the British Universities are honestly endeavouring to impart this knowledge of principles. Even though I run the risk of being accused of special pleading, I think the increasing attention given to physical chemistry at our Universities has contributed in the past, and will in the future still more powerfully contribute towards bringing the chemical teaching of our Universities into closer contact with that theory which technical practice requires, and which must rule successful technical practice. The name, physical

chemistry, is an unfortunate one, because physical chemistry is pre-eminently the science which studies the principles governing chemical actions. The science of chemistry as it is to-day was founded some hundred years ago by studying two physical properties of matter, namely mass and volume, by means of accurate physical instruments. The modern chemistry of to-day has found it necessary in the study of chemical action to employ many other so-called physical properties measured by means of many other accurate physical instruments, such as spectrometers, polarimeters, refractometers, galvanometers, electrometers, etc. Hence the rather misleading name of "physical" chemistry, which often conveys a very wrong idea of what is meant. A vast amount of physical chemistry is concerned with the determination of the chemical affinities of substances under all possible conditions. It seeks to answer the *fundamental* question of technical practice: given certain substances in certain conditions of temperature, pressure, and concentration, what reactions will take place, to what extent will they take place, and how speedily will this occur? You are all aware how in the past history of chemical science, Geoffroy, Bergmann, Berthollet, Berthelot, Guldberg and Waage, Van't Hoff and many others have sought to find an answer to this question of questions. After many years of labour, modern physical chemistry is only slowly, but nevertheless surely, arriving at the solution of the problem. I will conclude this special pleading by giving you an example, but it is one which is peculiarly appropriate here. It is possible, as Nernst and Haber have shown, to accurately calculate the maximum output of the Deacon chlorine process under any conditions of temperature, pressure, and initial composition of the reacting gases. This calculation is based on measurements of the dissociation of water and hydrochloric acid at high temperatures, and on measurements of the e.m.f. of galvanic cells. One begins to fore-see a time when it will be possible for the technical chemist to design from theoretical principles, a plant to satisfy a given specification, just as engineers would nowadays design a dynamo or a bridge. I think that physical chemistry will be one of the main contributors to that consummation.

Whilst thus emphasising the necessity of teaching the young chemist to think in terms of modern chemical theory, I do not suppose anybody will imagine that I am advocating the abolition or reduction of practical laboratory work. Of that sort of training the young chemist cannot get too much. This matter is so well understood now-a-days, that it is unnecessary to enter into it here. Physical chemistry cannot certainly be accused of negligence in this respect, for the undergraduate who studies physical chemistry generally finds this science almost too practical for him, inasmuch as he requires to add to his accomplishments in analytical chemistry and general chemical manipulation, a practical knowledge of working in glass, metal, and wood, and a much greater skill and dexterity of manipulation in the construction and handling of apparatus.

Let us assume then that the young chemist has received a sound training in the principles of chemical theory, and has gone through good courses of practical laboratory work in inorganic, analytical, physical, and organic chemistry. It is necessary that he should also have studied mathematics and physics. Very few people seem to realise how necessary a competent knowledge of mathematics and physics is to the future technical chemist. Every scientifically treated technical process involves this knowledge, and as chemistry is now rapidly becoming a dynamically as well as statically exact science, so the necessity for employing the weapons of exact science correspondingly increases. The technical chemist who cannot use the elements of the differential and integral calculus will soon become as extinct as the Ichthyosaurus. It is a welcome and significant sign of the times, that when an eminent chemical firm advertised some time ago for chemists, they required the candidates to possess a good knowledge of mathematics and physics. I am afraid many of our young University graduates in chemistry would find considerable difficulty in satisfying those conditions. There is certainly considerable room for reform here. It is also necessary that the young chemist

should be able to read German and French, and if possible Italian. He should come to the University from school with, at any rate, a reading knowledge of German and French. French of a sort is generally taught, but schoolmasters seem to regard German as a luxury. I know of one large school where a boy may take as extras (*sic*) either Chemistry or German, but not both. Such is the ignorance of the schoolmaster. This is not the place to enter into a discussion of the various subjects of literary and educational value which our future technical chemist might or should study at the University. The main difficulty here is the question of time, so far at all events as the majority of students at the newer English Universities are concerned.

We come now to the "bulk" co-ordinate, to chemistry allied with engineering, as carried out on the large scale in works. I do not think it advisable for Universities to organise lecture courses and build laboratories designed to meet the wants of specific industries. In the first place, such lectures, to be of any real value, must be given by those actually engaged in the industry in question, and such men are not available in England. In the second place the laboratories and their equipment would be very expensive, and would tend rapidly to become obsolete. The special knowledge and experience required for a specific industry are best gained, I think, in the works itself. It might be enquired, however, whether it would not be possible and desirable to have at a University a sort of laboratory of general applied chemistry, filled with some of the general apparatus of chemical engineering, everything being adapted to carry out operations on, say, a one-ton scale. In fact the whole laboratory would constitute a small experimental plant suitable for investigating a large number of chemical processes on a "small big" scale. There is something to be said for such a plan; if a squad of students were to quantitatively study chemical reactions in a laboratory of this sort, there is no doubt that they would have an opportunity of being introduced to the "bulk" or "dollar" co-ordinate, and of learning something about the apparatus employed in chemical engineering. I believe Professor Travers, in co-operation with Professor Rudolf, is erecting such a laboratory at the Indian Institute of Science at Bangalore, and I have no doubt that these gentlemen will make it a great success. Personally I think the idea is one well worth serious consideration, and so I hope that many of those who are present here to-night, and who are familiar with the stages through which a technical process goes on its way from the laboratory to the large works plant, will express their opinion on this subject.

There is another aspect of this important question on which I should like to hear the opinion of those who are engaged in chemical industries. As I have said before, works operations appear to me to be chemistry plus engineering. Is there not some minimum of knowledge concerning engineering in general which the University chemical graduate should possess? For example, every chemical industry requires power, and that brings one at once to questions concerning fuel and fuel economy, steam-raising plant, steam engines, gas-producers, and gas and oil engines, electrical generators, water and its purification, and so on. Is it not desirable that the technical chemist should know something about these things, since whatever sort of works he may enter, he is bound to have to deal in some way or other with the cost and production of power? Personally I am of opinion that every future technical chemist should, if possible, gain some theoretical and practical knowledge (a) of fuel and fuel metallurgy, and furnace construction; (b) of the construction, testing, and use of steam-raising plant, steam engines, power gas producers, and gas engines; (c) of the construction, testing, and use of dynamos and electrical motors. Such knowledge, to be useful, should if possible be combined with some training in the general principles and types of machinery and machine parts, the use of tools, and the elements of engineering drawing. It is of course impossible to make the young chemist a fully trained engineer of any of the usual types. He will never be expected to design steam engines, or electrical motors. But if in his subsequent career he is to take his proper place in industrial work, he will

have to design chemical engineering plant and supervise the carrying of laboratory processes through all stages up to large works plant. He will be constantly face to face with questions concerning the cost of power and the economy of fuel and power producers. If he is not to become the slave of the engineer, the technical chemist must know a great deal about these things, and that knowledge should, I think, begin at the University.

I have referred above to a knowledge of fuel and metallurgy. Now we cannot expect the technical chemist to be, in general, a fully trained metallurgist, any more than a fully trained engineer. But I think he should possess some acquaintance with the properties of metals and alloys, as they are dealt with by the modern scientific metallurgist. In his subsequent career he cannot escape from metals as essential materials of construction, and he should know something more about them and their properties than can be gained from the ordinary courses of inorganic chemistry.

I have endeavoured in the preceding remarks to indicate that sort of scientific knowledge which might profitably be added to a training in scientific chemical principles. I believe that the knowledge of metallurgy and engineering to which I have referred would form the best foundation on which the young chemist could subsequently build his wider knowledge and experience of chemical engineering and works plant. I am also inclined to believe that it would be more beneficial to him in general than any attempt at a University to teach him so-called "applied" chemistry, *i.e.*, the technical details of specific industries.

But this is again one of those points on which criticism and advice are most desirable, and I hope they will be forthcoming.

I come now to the "dollar co-ordinate," to the question of economic production and commercial possibility. This is undoubtedly the most difficult and complex factor of technical success. But it is essentially *the* factor, the one which dominates all others. Can the University do anything towards preparing the young chemist in this respect? That is a very difficult question to answer. It is of course possible to include in the practical laboratory courses certain exercises involving cost of raw material and power, as well as chemical efficiency and output. Electrochemistry in particular offers a wide field for the setting of most interesting practical exercises of this sort. In this way the extra variable may be introduced, and the mind of the student accustomed in some slight degree to the consideration of the financial aspect of chemical processes. Usually, however, one cannot go very far in this respect, not indeed much further than the suggestion of possibilities. To technical men this sort of thing may seem like mere play, but I think a little of it is beneficial, as it infuses a variety and actuality into laboratory work, and does no harm to the purely scientific aspect. But there are, it appears to me, two ways in which the University graduate might receive fuller and more serious training in this branch. In the first place, lectures might be given at the University by men actually engaged in chemical industry, on the commercial and financial aspects of economic production. After all, a chemical industry is chemistry + engineering + business. Business is the third co-ordinate, the third variable. The young chemist ought to learn something about business and business methods in general and about the finance of chemical business in particular. The University graduate ought to be a man who is going to deal with things of that sort at some future period of his career. Generally speaking, he has had no business experience when he comes to the University, and has no time or opportunity afterwards to spend a year or two in an office. Here then is another of those points on which criticism and advice are earnestly sought. I might mention that we are fortunate in Liverpool in possessing a School of the Science of Commerce in connection with our University. If the lecturers to which I referred above are not available, possibly the University chemist might make some use of the School, just as he might and ought to make use of the Department of Engineering, as I have suggested previously.

In the foregoing remarks, I have endeavoured to analyse the complex nature of the preliminary training

required for technical chemistry. It may appear strange to some of you that I have made no mention of research. The reason is that I have taken it for granted. As Sir William Ramsay has well said, research is chiefly valuable to the student for the attitude of mind it produces. It is a psychological necessity. There is so much to be learnt nowadays both practically and theoretically, and the time is so short, that the text-books, laboratories, and teachers must necessarily be in this connection more or less efficient machines for rapidly imparting to the unfortunate undergraduate his heritage of the ages. During this period a great deal may be done to correct false mental attitudes, but after all the stern necessities of the case exclude much heuristic dallying. The result is that the ordinarily intelligent and industrious student has comparatively little difficulty in obtaining his B.Sc. degree. So far all is well. But before he enters the works it is necessary for the student to realise three things, namely that what he knows is as nothing compared to what he doesn't know, that the learning of knowledge is a great deal easier than the making of knowledge, and that quiet, systematic, quantitative variation and control of conditions combined with correct logic and continuous thinking is the way knowledge is made. He learns these things by carrying out some research, be it big or small, be it "pure" or be it "technical." His whole mental attitude probably changes. He begins to realise that the business of the technical chemist is as much the manufacture of new, as the adaptation of already existing knowledge. He learns to adapt himself to new conditions without regret and without surprise. All this is so well understood and practised nowadays at our Universities that it would be an impertinence on my part to labour the point. But there is one thing to which I should like to refer briefly before passing on. Some people may perhaps regret that research at our Universities is not more closely connected with questions of immediate practical interest. In this connection, Dr. Bovey said in the address to which I referred previously, "We may take it, in fact, that there will be less waste in the world's advance if the scientific man is influenced in the choice of his research by practical necessities, and if the practical man is influenced by pure science so as to be interested in and to recognise the light which may be shed on scientific relations by accidental or intentional changes of circumstances in the course of his work." This is a fine ideal and well expressed. But how is it to be carried out? As Professor Kipping has informed us, Professor Duncan in America has induced several manufacturers to found scholarships for the purpose of researches on specific technical questions. So far as Universities are concerned, I am inclined to believe that this might be a dangerous and possibly harmful precedent. The true function of a University is to impart and to increase knowledge primarily for its own sake, and to give the student a true perspective and a wide horizon. Should, however, a manufacturer apply to a University for advice and help, I do not think he will often be refused. Research on a question of immediate technical importance is just as interesting and instructive as research on any other question. I think in fact that our manufacturers would do a great deal of good if they would indicate to the Universities the general lines of scientific enquiry which might be of commercial value to the country at a not too distant future. But so many delicate questions of personal interest, patent rights, and publication inevitably creep in here, that I believe the maximum good will in the long run be gained by our manufacturers (in the manner employing University graduates in their own well-equipped laboratories to investigate special technical questions. It would, however, do the University laboratory all the good in the world to be occasionally associated with the works laboratory in the elucidation of the problems presented by practice. But is this a practical proposition? Or can it be converted into one? Here once more is a question on which the opinion of our manufacturers is exceedingly desirable. For my part I think that research at the Universities should be untrammelled, that it should proceed on its own natural lines of development, but that technical applications of new scientific truths should neither be lost sight of nor despised, and the University

staff should, without unduly interfering with the private practice of the consulting chemist, be ready and willing to give advice to manufacturers on questions with which their own work has made them specially familiar.

After this digression I will proceed to mention one remaining point, namely the time to be spent at the University. Allowing three years for the preliminary training in chemistry, physics, mathematics, and modern languages (not to mention other subjects), and two years for research work together with the study of engineering and business, I think the minimum time required is five years. If a young fellow comes to the University at 18 (and I certainly think he ought not usually to come at an earlier age), he will have completed his University work at the age of 23 or 24. There will be then a fair chance of his mind having had time to mature before he enters the works, whilst at same time he will not be too old to adapt himself readily to his new surroundings. In conclusion I wish to say that although I have put forward a sort of a scheme, I have done so chiefly in order to present a basis for discussion. I fully realise that any scheme of this sort suffers from the fact that it is a scheme. All rigid educational schedules fail to allow for the natural variations of different minds, and for the varying nature of external conditions. It may be argued that alternative courses should be allowed, that two years of chemical research alone would be better than playing with engineering, that most of our big chemical works never require any engineering or business knowledge on the part of their chemists (at all events at first), and so on. Well, I will not spoil the discussion by endeavouring to disarm criticism. Although my chief idea in writing this paper has been to elicit an expression of opinion from others, I will not conclude without summing up my own. I think that what the future technical chemist requires, is not so much a better knowledge of analysis, chemical manipulation, or chemical facts—he usually get as much of these excellent things as the limited time permits—but a better and wider grasp of modern chemical theory, together with some idea of metallurgical, engineering, and commercial science. I will not conceal my opinion that this better grasp of modern chemical theory can only be gained by combining with the usual excellent courses in inorganic and organic chemistry a much more thorough-going study of what is commonly, but improperly, called in this country, physical chemistry. By this I mean the study of the relations between matter and electricity, the inner mechanism of chemical combination and valency, and the laws of chemical affinity, equilibrium, and velocity of reactions. I believe that if the future technical chemist is not so perfectly familiar with these things that he can reason and think in terms of them, then he will be heavily handicapped in the race. I hope no one will misunderstand me so far as to think that I in any way desire to underrate the importance of a thorough knowledge of every branch of chemical science. There is, after all, only one chemistry, and any one-sided study of this great subject is bound to be injurious.

DISCUSSION.

Dr. E. K. MUSEPRATT said the first question he asked himself was: What was a technical chemist? That term would embrace any number of people following chemistry, in any number of directions, and no training could be satisfactory which did not embrace the field covered by some one of those different directions which the technical chemists might ultimately pursue. For instance, an analytical chemist, who was consulted by various manufacturers as to what was best to be done in their own special manufacture might be one. Those actually engaged in brewing, dyeing, and tanning did not require exactly the same training as those who were engaged in making the larger chemicals, or in applying electricity to the production of chemical products. A technical school might have special classes for teaching dyeing, tanning, and even brewing, but even then the students must have a general training in the principles of chemistry. But when it came to the manufacture of the larger chemicals, the iron and steel industries, and in metal-

lurgy of all kinds, a very different training was required. The first two or three years must undoubtedly be devoted to thoroughly acquiring the principles of chemistry, physics, mechanics, and the higher mathematics. Mathematics should have been learnt in secondary schools, and the matriculated student ought to have a fair grounding in mathematics even as high as the differential and integral calculus. With that foundation, the student might possibly know what was the bent of his mind, and might then, under proper University teaching and the guidance of his Professor, be able to select his future course. For engaging in the manufacture of the larger chemicals, the student should require some of the principles of engineering; though it was not to be expected that he could become a perfect engineer. He should also thoroughly grasp the principles of electricity and its application in chemistry. He should also read something of the history of the developments of chemistry in these particular branches. Anyone, for instance, who read Dr. Frank's lecture, "The Application of Chemistry to Agriculture" (this J., Nov. 30, 1908), would see that ever since Liebig in 1840 first wrote his book upon the application of chemistry in agriculture, there has been a constant progress in that application.

Research should not be too intimately connected with any particular manufacture. Here and there, it might be of some advantage, but the great importance of research was, in the words of Sir William Ramsay, "attitude of mind." The student who had taken his degree even "with honours," should not think his training at an end. The very fact of his being put to undertake original research—to discover if possible some new idea, some new fact, should give him that "attitude of mind" which would teach him how to proceed when, in any works into which he might come, some industrial research was needed. The student, who had finished his course and taken his degree, should, therefore, have one year, or possibly more, which he should devote to chemical research. After all, very much depended upon the teacher. Among the most valuable qualities a chemist who desired to improve and increase the industry in which he was engaged could possess were enthusiasm and imagination. That enthusiasm could be communicated by the Professor who superintended the studies.

Dr. J. RASCHEN wrote:—"It is only after a considerable time that a University man will become useful to the manufacturer. This time will depend on local conditions and may be short in a works where every opportunity is offered and tendered for acquiring practical knowledge, and very long in a works where this is not the case. This, to a certain extent, might be remedied in the training of the student and make him indifferent to which class of works he first goes."

"The awkwardness displayed by a man fresh from the University is very noticeable when asked to put together certain apparatus with the object of research in a special subject for manufacturing purposes, or when, as so frequently happens, an investigation of a certain patent may be necessary, and works conditions have to be repeated in the laboratory. Such a man never tackles the subject in a proper manner, and the obvious inference is that something might be done in this direction in his training. A student should be set certain problems, for which many patents will serve the purpose, and be told to first of all design the laboratory experiment, and from that the necessary plant for manufacturing purposes. It may be said that this latter belongs to the engineering department. This is true to a certain extent, but the chemist has to supply the engineer with detailed information of what he wants, in what manner reactions occur, of what material the plant must consist, and what design of apparatus would be a suitable one. With this information the engineer will be able to design the actual plant."

Mr. J. W. CLAYTON said it was gratifying to find that Prof. Donnan had treated the subject with a humility which was somewhat rare. It was usually treated so one-sidedly by the director of a University laboratory, that manufacturers were kept from joining hands with the Professors in trying to improve matters. Prof. Kipping

tried to show that England was suffering very much from the decay of industry. At the annual meeting of the Society of Chemical Industry in 1883, the President at that time also deplored the decay of the chemical industry. A great deal of the want of success in technical chemists was due to the fact that when they took a position in a works, they immediately tried to show how much they knew. If when they entered a works they recognised that they knew nothing of manufacturing operations, and spent the first two or three years in cultivating their powers of observation, there would be very much less said against research chemists than there was now. There was nothing more annoying to a practical man who had spent the whole of his life in working at a particular process, upon which he had spent time and money, than to be dictated to by a man who had had no former experience. Too much time could not be spent in studying physical chemistry, which was a subject of the greatest importance. A great many processes had come to grief through some fact depending on physical chemistry and physical chemistry alone. He could not agree that chemical engineering must be learnt at the University. It was one of those things which could be picked up better in a works, if a man had had his powers of observation properly cultivated at a University. If he went in for engineering at the works and studied at a technical school at night, he would save time at the University and get a better knowledge when he is working with a big plant. Chemical engineering should not be interlarded during the student's chemical studies.

Professor Kipping had referred to technical scholarships, during which students should work out technical problems at the University under the supervision of a Professor, who could give them the run of a works; that was the basis of Prof. Duncan's scholarships and his theory. But Prof. Duncan's scholarships would find no application here, because students who were of any value at all would need the whole run of the works to grasp all the details and understand the process thoroughly, and no manufacturer would stand that.

Prof. J. CAMPBELL BROWN wrote as follows:—

"There is still a somewhat widespread idea that a student preparing for industrial work requires much less time to acquire his academical knowledge than those that are preparing for other occupations. Although this fallacy is not so universal as it was a generation ago, it indicates an entire misapprehension of what a University is. A man who is going to use his knowledge for the purpose of carrying out manufacturing processes and devising new ones, requires as wide an education as possible, and especially requires his information to be precise. Some years ago schemes of technological instruction were drawn up, including one for technological chemistry, in which an attempt was made to give a course of training in three years, of which two were to be devoted to pure science, and one to special branches of industrial chemistry. The schemes were not, however, carried into practice, and would never have been satisfactory. It is all very well for a man to be content with a two years' course of chemistry who is to spend his life in routine testing, such as a laboratory boy can be trained to do. An industrial chemist should be acquainted with the most advanced theoretical developments of pure science, that is to say, he should go through the honours curriculum of the Universities, and should have in addition a knowledge of the way in which large quantities of material are dealt with, the varieties of plant employed in some few selected typical manufactures, and above all, he should during the whole of his studies, after the elementary year, have his attention directed to, and his mind to some extent dwelling upon, the application of the knowledge he is acquiring to industrial purposes. There are manufactures so simple that they can be understood by any second year student, although the processes are very different from those performed in the test tube and in the laboratory; while other manufacturing processes require the application of the most advanced chemical philosophy for their elucidation. To put it briefly, an industrial chemist in order to be of value to his employers should be an honours graduate, and something more.

"It was with views such as these in their minds that some teachers of chemistry many years ago introduced selected

branches of industrial chemistry as alternative subjects, of which every candidate for honours in Victoria University must study at least one. I believe that all the Universities which have sprung from Victoria have continued this system, and although it is far from being an ideal one, experience shows that it has been of great value, and that so far as it goes, it proceeds on the right lines; but having got so far, we should now proceed further in the same direction. Every student who knows that he is to be engaged in chemical industries after he leaves the University, should pass at some stage of his curriculum under the direct guidance of a teacher whose function it should be to keep himself acquainted with: (1) the development of manufacturing processes, (2) the needs of the manufacturer, and (3) the researches which will tend to improve existing manufactures, and create new ones.

"For this purpose we require a new Endowed Chair of Industrial Chemistry, and it will undoubtedly be forthcoming—such chairs are absolutely necessary to the prosperity of a nation, and the progress of civilisation.

"It is often said that a man at college cannot be taught to feed a furnace or perform any of the other details of a manufacturing process; these things must be learnt at the works—of course they must, but the University can and ought to teach him the varieties of furnaces which have been introduced in the course of generations, the reasons for the modifications, and the principles which should guide him in the selection of the best for a given purpose. These things are best taught at the University, and they are not likely to be taught at the works. He may or may not pick up the information elsewhere.

"It has been truly said that no one Professor can cover the whole range of chemical manufactures, but that is no reason why he should not cover as many as he can; experience has shown that a student trained to be familiar with one branch of manufactures has been able, without any further special training, to take up and practise successfully another and different branch into which circumstances led him.

"In Liverpool we have, for the last 20 years, or nearly that time, endeavoured to devise means whereby students pursuing studies with a view of going into the industries, should at the same time get a certain amount of instruction in engineering, and many students have been advised to take engineering courses.

"Undergraduates, however, have found that if their curriculum is limited to three years, as it now normally is, there is no room for engineering studies, and only one now and again has been able to take engineering classes after graduation. The truth is that the establishment of a three-year curriculum for graduation which has become general, almost universal, in the present generation, is a great mistake, and if we could revert to the old four year curriculum, it would be a great deal better for students in after life."

Prof. CAMPBELL BROWN strongly supported what Professor Donnan had said regarding the advantages of a consultative connection between the manufacturers and the Universities. The embryo of such a connection had always existed, and its advantages had been obvious. But he did not share his fears that the practice of choosing a practically useful problem as a subject of research, might tend to narrow the horizon of the student. The narrowness or the wideness of his view would depend upon the student himself, perhaps on his teacher, and not upon the particular landscape which he was studying. For example, seven or eight years ago an old graduate, now in a works laboratory, mentioned to him the great need for a knowledge of the vapour tensions of sulphuric acid and water of high concentrations, and at higher temperatures than had been studied by Regnault. He afterwards gave this as a subject of research to two different men, each of whom worked on the subject, and published a paper. One man took the narrow view, and did not fully produce all the knowledge required; the other took a broader view and not only made a thorough investigation of the subject he started on, but was led by his work into a more extended investigation of another branch of the subject, and produced such an excellent paper that the University of London gave him the degree of D.Sc. for it. The industrial chemist started

the subject, the University man extended the knowledge and benefited alike the industry and himself, whilst science gained from both.

Mr. T. W. SUTHER was of opinion that technical chemists should be well grounded in general chemistry, physical chemistry, mathematics, physics, and an elementary knowledge of chemical engineering would be found very useful on entering works. Indeed the student's University training should be as thorough as his time and financial position would permit. On leaving the University, the student always found it difficult to go from the gram to the ton, the laboratory balance to the 20-ton weighing machine, and from the beaker to the steam boiler. What he understood by a technical chemist was not only the man who took charge of a works' laboratory and did research work, but the man who was destined to take the complete management of works in which large manufacturing operations were carried on. For this, a thorough scientific training at a University was most important, but to be a successful technical chemist, he must have graduated at another University—Nature's University, so to speak, and at birth be endowed with that natural ability, which was to be of such priceless value to him in after life. Natural ability, when of the right kind, provided him with common sense, organising and administrative ability, tact in getting on with others, push, force of character, and the capacity of getting work done by others. It enabled the technical chemist to manage himself as a starting point in the management of a staff of officials, and in the handling of men with whose duties he ought to be completely familiar, and know exactly the amount of wages to pay for work done. Natural ability, combined with scientific training, enabled the technical chemist, in time, to control the manipulation of material on the large scale, to erect plant, keep it in a state of repair, and to manufacture at the lowest possible cost, while maintaining a high standard of excellence of the products. Above all, he had to learn to constantly bear in mind that the sole object of all manufacturing operations is to make money. If the University student was fortunate enough to be endowed with sufficient natural ability to develop these qualities by many years of works' training and experience, and also combined with it the thorough University training which Prof. Donnan has suggested, then he was bound to be a successful technical chemist, provided he was afforded one thing more—the opportunity.

Mr. H. E. PORTER, speaking as a student, thought that research was one of the most important of the points which were raised by Professor Donnan. In the necessarily crowded state of a man's first years at the University, when he assimilated knowledge at a tremendously rapid rate, he had no time to think. It was in post-graduate years, while he was pursuing research work, that he was given breathing space to become more mentally alert. The true value of research consisted in this, that when a man was placed in a new set of circumstances, he would be able to adapt himself quickly, and thus do good work.

Mr. SOUTHWICK said that the teaching of business methods seemed to be quite out of the function of the University. As to research, much would depend upon the kind of technical chemist one was discussing. Was there not a great opportunity for Professors and Directors of Research to take up technical problems? By that he meant, not some definite problem that came into a particular works, but the problems of pure science. Take, for instance, the oil industry. There were many scientific problems in all branches. This would have another important influence, in that it would cement together the manufacturer in goodwill with the University. If the University to some extent allowed its men to take up some of these problems, the effect would be to attract the manufacturer to the University, such as he understood had happened in Birmingham.

Professor DONNAN, in summing up what had been said, concluded that the majority of speakers were against any special training in business methods, finance, or engineering at the University, considering that the student's time would be best spent in acquiring a sound knowledge of mathematics, physics, and chemistry, and in learning how to attack new chemical problems.

New York Section.

Meeting held at the Chemists' Club on Friday, February 19th, 1900.

MR. MAXIMILIAN TOLIN in the chair.

COLLOID CHEMISTRY AND SOME OF ITS TECHNICAL ASPECTS.

BY JEROME ALEXANDER.

Before discussing the technical aspects of colloids, it might be well to review in a general way some of the results of recent research on this interesting class of substances, the behaviour and reactions of which stand, so to speak, midway between the physical changes of matter on the one hand, and the chemical changes of matter on the other. Instead of referring to colloids as a "class of substances," it would perhaps be more correct to speak, as Graham does (*Phil. Trans.*, 1861, p. 183), of the "colloidal condition of matter," for many substances may exist in either the colloidal or the crystalloidal state, depending upon the nature of the solvent (e.g., certain soaps) or upon the conditions governing their formation (e.g., gold, sodium chloride, calcium carbonate, silicic acid, etc.).

With the aid of the ultramicroscope, which renders visible particles approaching in minuteness molecular dimensions, Zsigmondy has shown that there is no sharp line of demarcation between suspensions and solutions, but that with increasing fineness in the subdivision of the dissolved substance, there is a progressive change in the properties of the resulting fluids, the influence of gravity gradually yielding to that of the electric charge of the particles, and of other forms of energy. Thus, in the case of metallic gold, subdivisions whose particles are 1μ and over act as real suspensions and deposit their gold, whereas much finer subdivisions (60μ and under) exhibit all the properties of metal hydrosols or colloidal solutions. In the ultramicroscope the coarser subdivisions show the well known Brownian movement, which greatly increases as the particles become smaller, until at the present limit of ultramicroscopic visibility (about 5μ), it becomes enormous, both in speed and amplitude. This visual demonstration of the kinetic theory of solution justifies Graham's statement that "the colloidal is, in fact, a dynamical state of matter; the crystalloidal being the statical condition."

On the other hand there is no sharp distinction between colloids and crystalloids, but as the particles in solution become smaller and smaller, the optical heterogeneity decreases correspondingly, finally vanishing as molecular dimensions are approached. That even crystalloid solutions are not in a strict sense homogeneous, is indicated by an experiment of van Calcar and Lobry de Bruyn (*Rec. Trav. chim. Pays-Bas*, 1904, 23, 218; this J., 1904, 822), who caused the crystallisation of a considerable part of saturated crystalloid solutions at the periphery of a rapidly rotating centrifuge.

Not only does the degree of subdivision of the solute affect the properties of solutions, but the nature of the subdivided substance also enters as an important factor, producing a great multiplicity of colloidal phenomena. The fact that colloidal gold, for example, is precipitated by the addition of electrolytes is not because its particles are, as A. A. Noyes has suggested (*J. Am. Chem. Soc.*, 27, 97), larger than those of some other colloidal solutions such as gelatin and gum arabic, which are not similarly affected, but rather because of the specific properties of the particles themselves. Following Hardy (*Zeits. phys. Chem.*, 1900, 33, 326–385), Zsigmondy has expressed this difference by dividing colloids into two classes, the reversible and the irreversible, the former redissolving after desiccation at ordinary temperatures, whereas the latter do not. The following diagram, reproduced from Zsigmondy's book,* will make this classification quite clear.

* *Colloids and the Ultramicroscope* (English translation of *Zur Erkenntnis der Kolloide*). John Wiley and Son, N.Y., Chapman and Hall, London.

Rohland (Sprechsaal, 42, 1371) has investigated the effect of the addition of colloids to clay, and studied the modifying factors; he has also pointed out that highly plastic clays act like colloids (Zeits. Chem. Ind. Kolloide, 1907, 2, 177; this J., 1908, 27, 34). In French Pat. 387,803, Feb. 24, 1908, Keppeler and Spangenberg claim the addition of alkaline humus-like materials for the purpose of rendering clay more plastic and easier to cast (this J., 1908, 857).

These effects, together with the well-known superior sizing properties of glue and similar colloids which "free out" clay and make it "coyer" in surfacing paper and in kalsomining, are readily explained by the property possessed by reversible colloids of opposing group-formation and thus producing a fine grained structure.

Plaster of Paris.

Glues, gums, and other colloidal substances delay the setting of plaster of Paris, and "retarders" of this character have been in use for years. In order to show the nature of this retarding action, I prepared some solutions of the plaster and made microscope slides of each with the following results:—

1 part plaster to 1 part water con- taining per cent. 160 test * gelatin.	Time to set in minutes.	Microscopic appearance of slide.
0	40	Characteristic crystals of calcium sulphate.
1/100	50	No crystals, except in a few spots where some colloid free solution had diffused out.
1/10	260	No crystals.
1/4	510	No crystals.
1/2	960	No crystals.
1	Not set in 48 hours	No crystals.
2	Not set in 48 hours	No crystals.

* See this J., 1906, 25, 160.

Boiler scale.

In addition to containing various salts intended to precipitate scale-forming ingredients, most formulas for "boiler-compounds" and scale-preventing mixtures include such substances as glue, dextrin, starch, potatoes, tannin, extract of hemlock, etc. These colloids undoubtedly prevent the formation of hard crystalline scale, either by inhibiting to some extent the precipitation of the scale-forming salts or by keeping the precipitate in an extremely fine non-crystallising condition.

Soils and fertilisers.

Although from time immemorial farmers have classified soils on the basis of their physical and physiological character as "light" or "heavy," "rich" or "poor," "productive" or "unproductive," etc., it is only within comparatively recent years that chemists have begun to realise the full importance of the rôle played by the colloids, especially the organic colloids of the soil.

Many important properties of soils, such as permeability, capillarity, absorption, moisture content, etc., are dependent not so much upon the chemical composition as upon the size of the constituent soil particles. (See Atterberg, Schwed. landw. Akad., 1903, and Chem.-Zeit., 1905, 29, 195; Patten and Waggaman, U.S. Dept. of Agri., Bureau of Soils, Bull. No. 52, 1908.) In coarse sand, for example, the amount of water is greatest at the bottom and smallest at the top, whereas in fine clay the distribution is much more uniform.

Among the natural agencies tending to increase the size of the minute soil particles may be mentioned heat with its drying or evaporative effect, freezing, and the coagulating or flocculating action of soluble inorganic salts and of some organic substances present in the soil. On the other hand, included in that little known class of substances vaguely described as "humus," there are numerous organic substances derived from bacterial,

plant, or animal *debris*, or exuded by the roots of plants, which act as protective colloids (*Schutzkolloide*) and tend to produce and maintain the hydrosol in a diffuse or deflocculated condition. (See P. Ehrenberg, "Die Kolloide des Ackerbodens," Zeits. angew. Chem., 1908, 41, 2122). In an excellent paper on the mechanics of soil moisture, L. J. Briggs (U.S. Dept. of Agri., Bureau of Soils, Bull. No. 10, 1897), pointed out that very small quantities of certain organic substances such as are continually being produced in the soil by the decay of organic matter, greatly decrease the surface tension of solutions, thus counteracting to a large extent the effects of the surface application of soluble salts which would tend to draw moisture to the surface by increasing the surface tension of the capillary water of soils. It is well known, however, that an excess of salts will ruin a soil physically, as is evident after flooding by sea water or the continuous application of chemical fertilisers. Of interest in this connection is the recent work of the Bureau of Soils, U.S. Dept. of Agriculture, carried out by Cameron, Schreiner, Livingston, and their co-workers. Thus, in the case of the unproductive Takoma soil, green manure, oak-leaves, tannin, and pyrogallol greatly benefited plants grown in it. The injurious effects of quinone and some other organic substances may be due to their ability to precipitate or flocculate the protective colloids of the soil; for as Lumière and Seyewetz have shown (Bull. Soc. Chim., 1907, 4, 428—431; this J., 1907, 703), quinone renders gelatin insoluble.

The fact observed by Fickenday (J. Landw., 1906, 54, 343), that more alkali is required to flocculate natural clay soils than kaolin suspensions, he attributes to the protective action of the humus present (see Keppeler and Spangenberg, J. Landw., 1907, 55, 299).

A. S. Cushman, in his excellent work upon the use of feldspathic rock as fertiliser (U.S. Dept. of Agri., Bureau of Plant Industry, Bulletin No. 104; Cushman and Hubbard, J. Am. Chem. Soc., 30, 779), has shown that the fine grinding of feldspar increases the amount of potash available under the action of water. Thus a coarse powder having an area of 43 sq. cm. per c.c. of solid feldspar yielded 0.013 per cent., whereas a fine powder whose area was 501,486 sq. cm. per c.c. yielded 0.873 per cent. of potash and soda. These fine particles averaged about 0.1 μ in diameter, which is relatively large as compared with colloidal dimensions; but under the action of physical and chemical soil agencies they undergo further disintegration, finally reaching a colloidal condition in which still more of their potash is available, a condition favoured and maintained by the organic protective colloids of the soil.

With these brief and inadequate remarks I must dismiss this subject of such vast importance and fascinating interest, referring to the extensive literature, much of which is quoted in the Bulletin No. 52 and the other publications of the Bureau of Soils.

Electroplating and electrodeposition of metals.

As might well be expected from the experiment with lead nitrate previously referred to, the addition of protective colloids to electroplating baths tends to the production of fine grained non-crystalline deposits. A. G. Betts, in a paper entitled "The phenomena of metal depositing" (J. Am. Electrochem. Soc., 1905, 8, 63), has shown that there are many factors influencing the action of the colloid, and has suggested a number of possible explanations. The correct explanation, however, has been given by Müller and Bahntje (Z. Elektrochem., 1906, 12, 317; this J., 1906, 484), who state that the added colloid keeps the deposited metal (copper) in an amorphous, non-crystalline condition, gelatin producing the most powerful effect, egg albumen considerably less, while gum and starch have comparatively little action. They also found that the deposited copper weighed about 0.2 per cent. more than under normal conditions, indicating that some of the colloid had been carried down with the metal.

The relative efficiency of the colloids just referred to, corresponds to their relative efficiency in protecting from coagulation solutions of colloidal gold (see Zsigmondy, this J., 1902, 192), which is additional evidence that we

have here another instance of protective colloidal action, by which the crystallisation forces of the metal are powerfully influenced.

Metallurgy.

Since coarsely crystalline metals are brittle, tending to split along the lines of crystal cleavage, various physical and chemical means are employed in technical practice to obtain a hard, fine-grained structure (see P. Longmuir, *Iron and Steel Inst.*, Sept. 1907; this J., 1907, 1094). Among the physical methods are chilling and rolling, while the chemical methods involve the removal of undesirable constituents (as in the conversion of pig iron into steel), or the addition of desirable constituents (as in case-hardening, and the manufacture of "chrome steel," "nickel steel," etc.). For example, P. Pütz has shown (this J., 1907, 614) that the predominant effect of vanadium in steel is to decrease the size of the ferrite grains and make the material harder; it renders the ordinary structure due to pearlite fine-grained and homogeneous. (See also Beilby, *Proc. Roy. Soc., A*, 79, 463; this J., 1907, 926.)

Now, while the question is one of very great complexity, many of the facts at present available seem to indicate that one of the causes favouring the fine-grained structure, is the inhibition of crystallisation by substances colloiddally dissolved in the molten mass. Thus, part of the carbon is iron and steel exists in the graphitic form, and as graphite is slightly soluble in iron (see C. Benedicks, *Metallurgie*, 1908, 5, 41; this J., 1908, 406), some of it will, under proper conditions, be found in colloidal form (Carnegie Research Reports, this J., 1908, 27, 570; F. Wüst, this J., 1907, 26, 412; Hersey, this J., 27, 531). Besides metals may dissolve each other and other substances colloiddally, but in the case of ordinary metals this is not easy to demonstrate, although a differential solvent acting in the presence of a protective colloid might leave a colloidal residue.

An observation I recently made is of interest here. Moissan (*Comptes rend.*, 144, 593; this J., 1907, 413) has noted that the addition of a little platinum to metallic mercury causes the latter to "emulsify" in water. Upon making up such an "emulsion," I noticed that the supernatant fluid remained turbid upon standing and therefore examined the fluid in the ultramicroscope, which revealed the presence of colloidal metallic particles in active motion.

Dyeing.

The difference between a physical mixture and a chemical compound is frequently illustrated by dissolving out the sulphur from a mixture of iron filings and sulphur dust, and showing that the solvent, carbon bisulphide, does not affect the compound, ferrous sulphide. That in many cases dyeing is due, not to chemical combination, but to an absorption of the dye by the colloidal fibre, is evident from the fact that some dyestuffs can be extracted from the dyed fibre by means of alcohol. Investigation has shown that many dyes are colloidal in solution, and the selective colouring of various fibres, tissues, cells, nuclei, etc., is probably due to the selective absorption or precipitation of one colloid by another. The ultramicroscopic researches of N. Gaidukov (*Zeits. angew. Chem.*, 21, 393) support this view.

The phenomena of dyeing are rather numerous and complicated, for the dyestuffs are numbered by thousands, and the various fibres, tissues, etc., such as cotton, silk, wool, linen, jute, and straw, all react characteristically. In some cases the colloid fibre absorbs the dye, as with basic colours which dye silk and wool directly; in other cases there is necessary a mordant which is first absorbed and then fixes the colour. Certain colours mutually precipitate each other and may in fact serve as mordants for each other; e.g., methylene blue and dianil blue 2 R.; patent blue V and magenta.

Colloid chemistry also throws much light upon many obscure points in the practical art of dyeing. It is possible to obtain much more level colours in old dye-liquors than in fresh ones, and here it seems to me that colloiddally dissolved substances are responsible, exercising a restraining action upon the absorption of the colour. The addition

of Glaubers' salt facilitates level dyeing, probably by its action as an electrolyte, producing a partial coagulation of the dyestuff, so that the particles of the latter, thereby made larger, are absorbed more slowly and evenly.

In the production of colour lakes glue or gelatin is frequently added to bring about the formation of a fine-grained precipitate of great covering power. (See Zsigmondy, p. 62.) See also the following references to some of the recent work on the theory of dyeing:—Krafft, *Ber.*, 1899, 32, 1608; this J., 1899, 757; W. Biltz, this J., 1904, 23, 439; 1905, 24, 920; Biltz and Fiescher, this J., 1906, 25, 118; R. Willstätter, this J., 1904, 23, 1085; Freundlich and Losev, this J., 1907, 26, 682; Freundlich and Neumann, this J., 1908, 27, 935; Pelet and Grand, this J., 1907, 26, 920; Pelet-Jolivet and Anderson, *Z. Chem. und Ind. Koll.*, 2, 225, this J., 1908, 1149; des Bancelles, this J., 1906, 25, 852; Pietron and Linder, this J., 1906, 25, 67; Teague and Baxton, this J., 26, 1081; 27, 441; Lewis, this J., 1908, 27, 330.

Soap.

In a comprehensive paper entitled "Modern views on the constitution of soap," read before this section (see this J., 1907, 26, 590), Lewkowitsch epitomises the views of Merklen substantially as follows: "Commercial soap is a product having an essentially variable composition dependent upon (1) the nature of the fatty acids, (2) the composition of the 'nigre' (in the case of settled soaps), (3) on the temperature at which the boiling is conducted: it behaves like a colloid, and should not be regarded as a compound of sodium salts of fatty acids with which a definite amount of water is combined chemically, but rather as an 'absorption-product' whose composition is a function of the environment in which the salts of the fatty acids happen to be at the moment of the finishing operation."

Merklen's views conflict with the views as to the chemical composition of soap previously advanced by Lewkowitsch, who states, in conclusion: "But whatever may be the outcome of renewed experiments, Merklen's views cannot fail to stimulate further research into the composition of soap, and thus help to raise the industry of soapmaking, which has too long been looked upon as a mere art, to the rank of a scientifically well-founded industry, the operations of which are governed by the laws of mass action, the phase rule, and the modern chemistry of colloids."

The colloidal nature of soap solutions is indicated by their turbidity and their gelatinisation. That the detergent action of soap is consequent upon its deflocculating effect was brought out in the interesting Cantor Lecture of H. Jackson (*J. Soc. Arts*, 55, 1101 *et seq.*), who examined microscopically the supernatant fluid resulting from washing a dirty cloth with soap and water, and found in it countless particles in a state of oscillatory motion ("pedesis"). When an individual fibre was bathed in soap solution, the dirt particles gradually loosened and began to oscillate; upon substituting salt solution for the soap, the particles flocculated and the motion ceased. An ultramicroscopic examination of the detergent effects produced by soap should prove of interest. In this connection I must make mention of the excellent paper of W. D. Richardson on "Transparent soap" (*J. Amer. Chem. Soc.*, 30, 414), which he terms a supercooled or supersaturated solution, having distinctly crystalline tendencies, and exhibiting colloidal properties. Having in mind the fact that the salts of the higher fatty acids dissolve in water as colloids, and in alcohol as crystalloids (S. Ya. Levites, *Zeits. Chem. Ind. Kolloide*, 2, 208 *et seq.*; this J., 1908, 1134; Mayer, Schaeffer, and Terroine, *Compt. rend.*, 146, 481), and also the fact that alcohol or equivalent solvents (glycerol, sugar, &c.) are used in transparent soap, it seems probable that the crystals which frequently form in it are due to the slow separation of such part of the soap as is in crystalloid solution. This view is supported by the fact adduced by Richardson (*loc. cit.*, p. 418), that the fatty acids separated from the crystals had a higher melting point than those separated from the clear matrix. The isolation of the crystals was difficult because of their ramifying tendency, which recalls some of the crystal-figures exhibited by some of the mixtures of crystalloids and colloids previously referred to.

What we may call the crystalloid phase of soap is apparently governed by the same factors as those which Tamman has pointed out as governing the crystallisation of supercooled solutions, i.e., 1st, the specific power of crystallisation; 2nd, the speed of crystallisation; 3rd, the viscosity (see Zsigmondy, p. 128 *et seq.*). Thus, gold ruby glass when quickly cooled (or supercooled) is colourless, but acquires a red colour upon reheating to the softening point. By ultramicroscopic examination Zsigmondy showed that the nuclei of metallic gold, which in the colourless glass were amicroscopic, grew into ultramicroscopic visibility in the red glass. It therefore seemed to me that a most important factor in determining the transparency of transparent soap would be the speed of cooling, and some experiments were made along this line.

A piece of commercial transparent soap was melted and cast into two cups, one of which was quickly chilled in ice, while the other was allowed to cool slowly by immersion in hot water. The quickly-cooled piece was transparent, while the other was practically opaque, and showed upon ultramicroscopic examination much larger ultramicros than the transparent piece.

Milk.

That casein exists in milk as an irreversible colloid, and can be protected by reversible colloids ("Schutzkolloide"), I have shown by the following experiment: Skim milk was diluted with water and divided into two parts, to one of which was added a little liquid glue or gelatin. The two solutions were placed in boiling tubes and acidified slightly with acid (acetic or hydrochloric). The tube without the added colloid cleared up rapidly, the precipitate formed rising to the top and leaving the fluid beneath quite clear. The tube containing the added colloid, while eventually showing some precipitate, remained milky even after several weeks' standing. Since writing the above, the ultramicroscopic observation of Kridl and Neumann (Physiol. Inst. Univ. of Vienna [Pflüger], 123, 523-539), also support the conclusion that the casein of milk is an irreversible hydrosol.

This view has an important bearing on the question of the modification of cows' milk for infant feeding, for it justifies the addition of reversible colloids such as cereal gruels, gelatin, etc., which had been opposed by some physicians on the ground that they were not normal constituents of mother's milk, or any other milk. But experiment shows that the curd resulting from the coagulation of woman's milk is much softer and more readily digested than that yielded by cow's milk, which, as an inspection of the subjoined table will show, indicates that the so-called albumin of woman's milk acts as a protective colloid.

Average composition.

	Woman's milk.	Cow's milk.
Water	88.20	87.1
Proteins (Casein (irreversible hydrosol) (Albumin (reversible hydrosol))	0.75 1.00	3.02 0.53
Fat	3.50	3.69
Sugar	6.20	4.88
Ash	0.25	—

To physicians it is certainly no novel statement that the addition of reversible colloids to cow's milk, very much increases its digestibility. Thus, Dr. A. Jacobi says ("The Intestinal Diseases of Infancy and Childhood" (1890), p. 62 *et seq.*): "There is no doubt, therefore, as to the utility of gum arabic and gelatin as an addition to cow's milk and to children's diet. Not only do they fulfil the indication of diminishing and distributing the particles in cow's milk, but they also officiate as a means of direct nourishment by preventing waste." He also points out that: "it was evident that the other ingesta were more completely digested, and that a smaller amount of excrementitious matter was discharged when gelatin was added than when omitted." In this case the added "protective" colloids act by preventing the formation

of large groups when the casein is coagulated by the acid juices of the stomach, so that the precipitate (if at all formed) is readily dissolved by the digestive enzymes. In fact, it may be that the coagulation of the casein is entirely prevented, for Jacobi remarks that milk, when mixed with gum arabic, bears the admixture of hydrochloric acid quite well. In his book on the "Diseases of Infancy and Childhood" (1902), H. Koplik states: "The amount of casein in cow's milk is not only relatively, but absolutely greater than in woman's milk. In describing woman's milk, it was stated that in cow's milk the casein forms five-sixths of the total proteids in the milk, whereas in woman's milk the casein forms two-sixths of the total proteids. This fact is of far-reaching importance. Simple dilution of cow's milk leaves it with a greater proportion of casein relatively to the other proteids than that which exists in human milk. Again, cow's milk precipitates or coagulates very early with the aid of acids and salts; woman's milk quite late, or not at all. Therefore, in the infant stomach cow's milk does not take up much acid of the gastric juice and soon coagulates in large masses. Woman's milk, on the other hand, takes up a large amount of acid of the gastric juice, and coagulates late in small masses. These differences in the modes of coagulation in the two caseins are of great importance in the study of infant feeding."

Further investigation is being made as to the nature of the chemical composition and the condition of subdivision of the casein in various milks, which have been assumed to be chemically different. Many reactions which have been held to indicate such chemical difference may be simply due to the presence of varying amounts of protective colloids, or to differences in the colloidal condition or aggregation of the same casein, consequent to some extent, perhaps, upon differences of reaction, or quantity of salts or enzymes present.

Ice cream.

It is a fact well known to practical ice cream makers, and amply proven by experience, that ice cream made without eggs, gelatin, or some similar colloidal ingredient is gritty, grainy, or sandy, or else soon becomes so upon standing; whereas ice cream made with small quantities of colloids possesses that rich, mellow, velvety texture so much in demand. Here the added colloid acts as an inhibitor of crystallisation or practically speaking as a preserver of texture. This was pointed out in a preliminary paper entitled "The Effect of Colloids upon Crystallisation," read before the New York Section of the American Chemical Society, April 10th, 1908, and published in the Zeits. Chem. Ind. der Kolloide, Feb., 1909. In this paper I also stated that the added colloid, especially gelatin, which is the one most generally used, may serve as a protective colloid in preventing the coagulation of casein, apparently an irreversible hydrosol and a normal constituent of ice cream. In view of what has been said above regarding milk, it is evident that gelatin thus renders ice cream more digestible. I convinced myself of this fact by making up two batches of ice cream under uniform conditions, one with and one without the addition of gelatin. I found the batch with gelatin smooth, velvety, and delicious, whereas the other was sandy, grainy, and unsatisfactory. I have observed the same sandiness in "Philadelphia" ice cream made from 22 per cent. cream, in which, chiefly for sentimental reasons, no gelatin had been used. The "French" ice cream of the same manufacturer contained eggs and was smooth and fine grained. (See also Liesegang, this J., 1908, 27, 634.)

A very misleading impression is given by some official food chemists referring to gelatin in ice cream as a "filler," which naturally leads to the idea that it is an inferior ingredient added in quantity to cheapen the product. But as gelatin is expensive, and as but 1 per cent. is used, such a view is evidently erroneous. The food value of gelatin as a protector of the body's nitrogen being generally admitted, and its effects in milk being very beneficial from a digestive point of view, its use in ice cream in the quantities referred to is necessary, legitimate, and scientific.

The above is of particular interest in view of the fact that the standard promulgated for ice cream by the U.S. Hon. Secretary of Agriculture acting upon the advice of the Committee on Food Standards, excludes eggs, gelatin, and similar colloids from this confection, thus making "illegal" French ice cream made according to old-established formulas. Most of the States fortunately do not accept the national standard, but permit each maker to use his own formula with reasonable limitations.

Confectionery.

In gum drops, marshmallows, "moonshine," and other candies, use is made of gum arabic, gelatin, albumen, and other colloids to prevent the crystallisation of the sugar. Thus, besides adding to the food value, they give the candy a smooth and agreeable taste, and preserve it in saleable condition.

Filtration.

The importance, in technical filtration, of the relation between the size of the particles of a precipitate and the size of the orifices in the filter, has been pointed out by Hatschek (this J., 1908, 27, 538). It is quite evident that the presence of protective colloids by tending to produce the fine or "hydrosol" condition may entirely prevent the filtration of a precipitate by ordinary means, and for this very reason the filtration of glue and gelatin liquors is practically impossible unless a flocculated "hydrogel" precipitate is first obtained. The work of Zsigmondy and Schulz on the filtration of gold hydrosols is of particular interest in this connection. (See also Bechhold, Z. Chem. und Ind. Koll., 1906, 1, 107; Z. physik. Chem., 1907, 60, 257; Biochem. Z., 6, 379; Bigelow, J. Am. Chem. Soc. 29, 1675; this J., 27, 93.)

Chemical Analysis.

The presence of colloids, especially in technical products or solutions, may lead to grave errors in analysis, so that the chemist should destroy them by ignition, or else nullify their effects by the addition of a sufficient excess of coagulant or precipitant. Reversible colloids, which are frequently referred to under the vague term "organic matter," may act: (1) by totally or partially preventing the formation of precipitates, just as tartaric acid and tartrates prevent the precipitation of alumina, chromic oxide, and ferric oxide (see Yoshimoto, this J., 1908, 27, 952); (2) by preventing the satisfactory filtration of the precipitate formed (see Mooers and Hampton, J. Am. Chem. Soc., 30, 895); (3) by rendering precipitates difficult to wash and purify (see Duclaux, this J., 1906, 25, 866).

A few experiments will serve to make clear the importance of these remarks. Three solutions of lead acetate were taken; to the first was added hydrochloric acid which yielded a heavy coagulated precipitate; to the second was added sodium chloride (a less highly ionized precipitant), which yielded a colloidal precipitate of lead chloride; to the third was added, first, a little glue solution and then sodium chloride, which in this case gave no precipitate at all.

Again, in the presence of glue, silver nitrate gives with sodium chloride only an opalescence which passes through filter paper. Even a large excess of hydrochloric acid fails to produce a precipitate. But upon adding to the solutions containing the colloid and chloride, some silver nitrate containing no protective colloid, a copious precipitation occurs at once.

Any number of experiments of this kind can be made; among those I have found of interest are:

Sodium thiosulphate	+ colloid + hydrochloric acid;
Calcium chloride	+ colloid + ammonium oxalate;
Lead acetate	+ colloid + zinc sulphate
Lead acetate	+ colloid + potassium iodide;
Lead acetate	+ colloid + potassium bichromate;
Magnesium sulphate	+ colloid + barium chloride;
Potassium ferrocyanide	+ colloid + copper sulphate;
Ferrous chloride	+ colloid + ammonia;
Hydrochloric acid	+ colloid + sodium thiosulphate;

This general and incomplete survey of some of the technical applications of colloid chemistry might

be extended indefinitely, for recent chemical literature teems with papers applicable to the subject. Thus, Fouquet (Bull. Assoc. Chim. Suer. Dist., 25, 1046) has discussed the removal of the colloids which in crude sugar prevent the clarification of the solution and crystallisation of the sucrose. O'Shaughnessy and Kimmersley (this J., 25, 719), and Fowler, Evans, and Oddie (this J., 27, 295), have discussed the importance of colloids in sewage disposal. Bayliss, in his excellent monograph on "The Nature of Enzyme Action," considers enzymes in the light of colloid-chemistry. Raschig has found (see this J., 1907, 26, 1108; c.f., also Cross, Bevan, and Briggs, this J., 1908, 27, 260) that the addition of a very small quantity of glue or gelatin to the reacting mixture greatly increases the yield of hydrazine. In weighting silk, gelatin is used to "animalise" the fibre, which it does by preventing the crystallisation of the salts used for loading, which would render the fibre brittle. (See Gnehm and Bünziger, this J., 1897, 16, 234; Jochen, U.S. Patent 792,218, this J., 1905, 24, 799; Meister, this J., 1906, 25, 128.)

The applications of colloid chemistry to tanning (see Westenfelder, Ilide and Leather, 25, 12; Herzog and Adler, this J., 1908, 27, 347; J. T. Wood, this J., 1908, 27, 384), to photography, to pharmacy, to the cement industry (see Gaines, U.S. Patent 883,683; Gresly, this J., 1908, 27, 1154), and to many other technical branches, are continually appearing in the journal and patent literature, to which those interested must refer. Among the investigators whose work in the field of colloid chemistry is of importance, may be mentioned Cotton and Monton, Bechhold, Billitzer, Biltz, Bredig, Coehn, Donau, Donnan, Duclaux, Ehrenberg, Freundlich, Hardy, Jordis, Kuzel, Levites, Lobry de Bruyn, Lottermoser, Michaelis, Müller, Nuthmann, Neuberg, Paal, Pauli, Quinke, Schulze, Spring, Svedberg, von Weimarn, Zsigmondy, and many others.

In conclusion, I would say that my object is accomplished if I have succeeded in exhibiting the great and widespread technical importance of colloids and the colloidal condition.

"COMMERS" IN HONOUR OF DR. H. SCHWEITZER.

On Saturday, March 13th, a "Commers" took place at the Liederkranz Hall, New York City, Prof. C. F. Chandler presiding, to celebrate the 25th anniversary of Dr. Hugo Schweitzer's Doctorate, the 20th anniversary of his arrival in New York, the 9th anniversary of the foundation of the Verein Deutscher Chemiker, and the completion of his 15th year of office as Hon. Secretary of the New York Section of the Society of Chemical Industry, when a presentation of plate was made.

Scottish Section.

Meeting held at Glasgow on Tuesday, February 16th, 1909.

MR. DAVID J. PLAYFAIR IN THE CHAIR.

THE FACTORS THAT CONSTITUTE VALUE IN TEAS.

BY W. CARRICK ANDERSON, M.A., D.Sc.

Although the growing and curing of tea is from beginning to end a chemical manufacture, and by no means a simple one, it is only of very recent years that chemistry has been allowed a place at any stage either in its cultivation or preparation. The pioneer work of Bamber in Ceylon and of H. H. Mann in North East India during the last decade has made a commencement in removing this reproach from an important industry by numerous observations made on the course of manufacture and by the publication of extended series of analyses of typical soils in which the tea plant flourishes and is capable of economic cultivation. Simultaneously the practice of manuring tea lands with artificial preparations more or less skilfully compounded has, in Ceylon particularly, been followed by results so remarkable in respect of heavier yields of leaf per acre as

largely to modify the scepticism with which in this, as in many another established industry, the rule of thumb manufacturer looked upon the ambitious advances of applied science. An increase in yield from, say, 400 to 600 lb. of made tea per acre on some estates within a few years as the result of artificial manuring has gone far to convince even conservative planters that the industry may have much to gain from a scientific study of its problems and particularly from an elucidation of the chemical changes that occur in the leaf before and during its manufacture into a marketable commodity.

Apart from increase of yield, however, it must be admitted that on the side of cultivation there is, up to the present, no very decided improvement that can be pointed to as the direct result of a scientific study of the question. That is to say, if we take increase in the average market price per lb. for the produce of an estate as the indication and measure of any such improvement, it is doubtful whether any unequivocal example is forthcoming of improvement in quality induced by manuring on so-called scientific lines which has been sufficiently marked to influence this average to the extent of $\frac{1}{4}$ d. or even $\frac{1}{2}$ d. per lb. On the other hand, it is a matter of common knowledge that on different estates the quality of the tea produced varies enormously, and that this variation is reflected more or less steadily in the prices obtained for it. Moreover this inequality exists even in cases where it cannot be charged to variety in the jāt or in the age of the bushes or to any difference in the degree of skill or the length of experience of those responsible for the management. It is traceable, in fact, entirely in many cases to variations in the resultant of forces that operate in the growth of the leaf which have their seat either in the soil or in the air or in the two together. A diligent inquiry, therefore, into the nature and relative values of these forces is bound sooner or later to bring to light the cause of the differences and to supply the necessary data for judging under what circumstances and to what extent the best conditions may be artificially created with due regard to the economics of the problem.

But again the resultant of the forces at work in air and soil which produces leaf of a particular quality is subject to further influence by the new forces brought to bear upon the leaf during the course of manufacture, which may have the ultimate effect of causing the most to be made of a certain quality of leaf that can be made, or of detracting more or less considerably from the potential value it possessed when it left the bush. Here the chemical problems, though complicated and difficult, are perhaps less abstruse than those to be handled in the case of leaf growth, and already a large amount of information exists bearing on the changes that take place in the withering, fermentation and drying stages of the manufacture. Though even here a beginning only has been made, there is little doubt that it is simply a matter of time till the whole series of operations in the tea factory is as thoroughly understood and as rigorously controlled as is the case in many other chemical industries that at one period were not less empirical in their ways of working. At present, variations in the quality of leaf give rise to a good deal of experimenting on most estates, the managers in some cases expending much ingenuity in devising alterations here and there that may or may not be beneficial, and in others modifying their processes as the result of hearsay regarding the supposed advantage that has accrued to some other estate through the adoption of a certain line of action.

In hardly any case is the course adopted based on any well-ascertained chemical data. It is purely empirical, and in the end has to stand or fall by what the general reports of the tea taster appear to indicate as to improvement or the reverse having taken place in the teas sent down from the estate to Calcutta, Colombo, or London.

There are two primary criticisms that may be passed on this sort of experimenting in the case of tea: (1) The factors that enter into the production of tea, good or indifferent, are very numerous, very variable in degree, and extraordinarily complicated in their interaction. (2) The qualities on which the market valuation is based are many, the importance attached to some of them is by no means always proportional to their amount, and their desirability in relation to one another, from a market point

of view, is not the same in different types of leaf. It is evident, therefore, that any alteration in the treatment of the leaf on the bush or subsequently may produce a series of changes of which some may be beneficial and some adverse, and that until the factors that collectively constitute value are differentiated and regarded, separately from one another, as contributing to the market price, there is no clear guidance available for those who would make systematic efforts towards improvement in the market valuations of their tea. The purpose of the present paper is to state briefly what these factors are, and in general terms to indicate their importance relatively to one another.

First of all, however, a word must be said on the position of the tea-taster. Since in the end the goodness of a tea is determined by the price it will fetch in the market, the services of the expert tea-taster are indispensable. He is the interpreter of the mind of the market, and speaks its wishes frequently with an accuracy that is astonishing. In arriving at his valuation he has to appraise the merits of a sample in respect collectively to flavour, pungency, thickness and colour of liquor, tippiness (if any), make or twist of leaf, and freedom from brown leaf or stalk, with allowance for any individual or local characteristics it may possess. He must also know the relative demands of the market at the moment for each separate grade of leaf, broken orange pekoes, broken pekoes, orange pekoes, pekoes, pekoe souchongs and fannings, and be able to value them accurately in relation to one another. That this can be done with the degree of precision that is sometimes shown speaks eloquently for the sensitiveness of a trained eye and palate, especially when one considers that in some establishments several hundred samples have to be tasted and valued per diem. On the other hand, the tea-taster discriminates only in a very general way between the elements that contribute to his valuation, if at all, and not to the extent or to the degree of minuteness that is required for the purposes of investigation or that is (in the case of some items at least) possible by chemical methods. For this reason, while samples must continue to be referred ultimately to the judgment of the tea-taster for his opinion on its market value, progress towards improvement will only become possible as systematic work in the laboratory is directed towards ascertaining (1) the chemical nature and origin of the bodies whose presence gives rise to one or more factors of value, and (2) the quantitative relationship in which each of these stands to market price.

Of the totality of factors mentioned above that enter into the market value of tea, one group is judged by the eye, the other by the palate, and in some cases the evidence obtainable by the eye probably carries the greater weight. It includes (1) Tip, (2) Twist or make, (3) Presence or absence of stalk and brown leaf.

By "tip" is meant that portion of the young shoot of the tea plant which consists of an unopened, or partially opened, bud developed under conditions such that, when properly handled in the subsequent manufacturing operations, it appears finally of a rich golden colour. Tip is a fluctuating quantity: largely seasonal and associated with some estates and districts to a much greater extent than with others. It is very easily diminished in amount, and may even be entirely obliterated in the course of the manufacturing operations, becoming of a dull brown or black colour, almost or altogether indistinguishable from the rest of the bulk. Its tendency is to disappear also on keeping, particularly where the tea has not been packed straight from the dryer or a final firing has been omitted. "Tip" shows principally in the fannings and broken orange, broken and orange pekoes: only in exceptional cases does it reach the pekoe grade. It is one of the consequences of the empirical valuation of teas by appearance that "tippiness" brings an altogether disproportionate addition to what might be called the real or intrinsic value of a sample: a broken orange pekoe, for example, which, if its liquor only were paid attention to, would be worth $\frac{1}{2}$ d. or 6d. per lb., might fetch 1s. 6d. per lb. in the market if possessed of a fine show of bright, golden tip. The conditions that give rise to tip are still obscure. It consists mainly of bud, but all buds will not yield tip, even with the most careful manufacture, while at other times a first leaf, in addition

to the bud, may in the finished tea be retained in the tippy condition.

Twist is another element that enters into the judgment of tea samples by the eye. To a large extent it is a sentimental consideration, a well-twisted pekoe, for example, having a neater and pleasanter appearance than one that is rough and bold in character. It is in itself no safe guide to the degree of care exercised in handling, still less is it to be taken as a criterion of relative merit intrinsically as between one sample and another. It may in one case indicate that the leaf has been underwithered from a mechanical point of view, so that it has been unable to retain the twist; in another that it has been too short a time in the rollers; and in a third that it has been very rapidly dried at a high temperature in the firing machine. Apart from the sentimental consideration, the evidence afforded by the twist of the leaf is useful only as collateral to the evidence of the liquor itself.

The presence of brown leaf or stalk in a sample of tea is the third point to which attention is given in an examination by the eye. It is due to the inclusion in the manufactured leaf of portions of the tea bush of such a character that during manufacture the chemical changes that normally take place in the stages of withering and fermentation have been able to progress in them only slowly and to a moderate extent, with the result that the finished leaf shows up brownish black, brown, or even red in colour, according to degree. Generally the presence of red leaf points to "free plucking," and the consequent inclusion of a proportion of leaves and stalks which have so far matured that the enzyme, on which depends the chemical changes that lead to the conversion of raw leaf into tea, has become greatly weakened in its action, and the changes in consequence neither go on with sufficient rapidity nor far enough to produce the bodies that, on subsequent drying of the leaf, will result in black tea. Since low-class teas at the best contain the enzyme in lesser degree than high-class growths, it follows that, apart from any greater tendency to pluck freely on low-class tea estates in order to make up in quantity what is lacking in quality, the chances are for red leaf to show itself more readily in the produce of such estates than of those in a quality district. The superficial inspection of a sample containing red leaf may, however, be very misleading as a means of estimating the extent to which this matured leaf, which is very inferior from a liquoring point of view, has been included, since it is possible in the manufacturing process to so mask its appearance by giving it a superficial darkening in colour, that it no longer obtrudes itself on the eye as red leaf. While this is not always a procedure to be recommended, since it is apt to result in a deterioration of the liquors as a whole, it may be justifiable in practice with many low-class teas where quality of liquor is of minor account compared with appearance, since in such a case the showing of a large proportion of red leaf in the sample might readily class them as unsaleable.

(2) The factors of value in tea that are judged by the palate belong of course to the infusion, and may be distinguished as (1) flavour, (2) pungency, (3) fulness or thickness of liquor and (4) colour. The last three, when appearing in fair quantity together, constitute "strength."

The flavour of tea, which is its most subtle and delicate as well as its most variable characteristic, is due to the products of the tea oil formed by enzymic oxidation at moderate temperatures. These bodies which from their sensitiveness to free oxygen as well as to liquid oxidants are probably aldehydic in character, are developed in the course of fermentation, and are very easily deteriorated or destroyed in the drying process. They are readily volatilised by steam, and, if the aqueous vapours from the drying leaf be condensed, the water smells strongly of the oil. The total quantity of oil contained even in the leaf yielding the most flavoury teas is very minute, and hitherto the quantities extracted have been insufficient to allow of an extended study of its properties. Schimmel's Report (40, 1897) states the proportion obtained as 0.006 per cent. The specific gravity is given as 0.866. The oil is said further to be slightly levo-rotatory and to be separable by distillation into two portions, one boiling below, the other above 170° C. The portion boiling below 170° C. was found to

contain a compound having a boiling point 153—154° C. and possessing a pungent, fusel-like odour. It appeared to be alcoholic in character.

Pungency, which in more or less degree is an essential quality of saleable teas, is associated with the presence of tannin-like substances in the leaf. After withering, and before rolling has commenced, the soluble cannoid bodies are usually at a minimum, but collectively they are of such a character as to impart a harsh and more or less bitter, coarse taste to the infusion. By the oxidising influence of the air, operating mainly during the period of fermentation, they are rendered more mellow and palatable, and, if the oxidation be not unduly prolonged, the harshness may be got rid of completely, or almost completely, while the liquor still retains sufficient astringency to "draw" the mouth and leave a clean feeling in it. The change is accompanied by the passage of a portion both of the tannins and analogous substances into the insoluble condition. The bodies which are oxidised consist presumably of that portion of the reserve material on which the fasting leaf has to fall back first of all after it is removed from the parent stem, so as to make good the loss sustained in respiration, and the agency employed is the enzymes which have been liberated during the starving process that went on during the continuance of the withering stage. When an infusion is said to be dull or pointless, this has usually been regarded as equivalent to saying that the proportion of tannins had been reduced to too low a figure in consequence of a rather prolonged oxidation or fermentation of the leaf. The case, however, is not quite so simple as this would appear to make it, and the desirable "point" or piquancy in the infusion, with at the same time a blandness or mellowness as an accompaniment, is probably as much a matter of the nature of the tannoid substances, consequent on the character of the oxidation, as of their absolute quantity in the infusion.

Fulness or body is a quality that, like flavour, is very variable in tea liquors. Fulness may co-exist in a liquor with a high degree of flavour, as in many North Indian teas particularly. On the other hand many flavoury teas are lacking in fulness, and again, in others, fulness may be a redeeming character when flavour is at a minimum. The development of a high degree of fulness is in many (perhaps in most) cases incompatible with retention of the highest flavour, and it is only where flavour is a marked feature of the leaf that manufacture is conducted with that as the prime object in view. In other cases, and especially in low country or common teas, the manufacture is guided by the consideration of strength in the liquors, of which fulness forms an important attribute. Where the enzyme is abundant and active in the leaf, a full liquor is not difficult to obtain even at the moderate temperatures which experience has shown to give the best all-round quality teas. But even in leaf deficient in enzyme fulness is still purchasable by conducting the fermentation at rather higher temperatures, and to some extent and within the capabilities of the particular leaf handled the only question to be answered is as to the price to be paid for it, since at these higher temperatures the oxidation of the tannin proceeds at an accelerated rate, and thus may readily induce dulness in the liquor. In the case of low-class teas, however, fulness appears so much of a desideratum that tannin oxidation may be pushed a considerable length, provided fulness is increased thereby, without detriment to the selling price. This would appear to be particularly the case in the European market, which will welcome almost any tea provided it is coloury and full, but will only tolerate a thin liquor if its fault is condoned by flavour. The cause of fulness is specific, and it is not in any way to be identified with the amount of soluble matter in the infusion. Indeed, a leaf may have 45 per cent. of its weight soluble in water on infusion, and yet be characterised as giving a thin liquor. Withering and fermentation together, when properly conducted, may actually lessen considerably the amount of matter in the leaf that is capable of going into solution in hot water, but, on the other hand, they impart to the resulting liquor more or less of the character of fulness. The body of the liquor is increased. The cause of this is to be found in changes induced in the nitrogenous constituents of the leaf during the processes of withering and fermentation. The tissues

of the young tea shoot contain (or rather develop during the process of withering) a protease which is capable, under suitable conditions, of acting on the albumens and converting them into soluble proteoses, and more especially into albumose, and it is to the presence of these bodies in quantity that the characteristic fulness or thickness of the liquors, such as are got from high-class Assam growths, for example, is primarily due.

The last element of market value of which mention must be made is colour. A large quantity of tea comes into the European market and finds a more or less ready sale there of which perhaps most has been told that can be said when it is described as giving a dark coloury liquor on infusion. In common teas this colouriness may be found without even very much fulness, and where the latter exists it has frequently been purchased at the expense of considerable loss of pungency in manufacture through the maintenance of "stewing" conditions in the drying stage. Many of the better class Assam growths, on the other hand, combine colour and fulness (even thickness) of liquor with a large amount of pungency as well. When these three elements co-exist in marked degree in a liquor it is stamped as "strong," and such strong teas, especially if possessed of appreciable flavour, are always sure of a ready market, at least in Europe. American demand, on the contrary, appears to go more in the direction of pungent, light liquoring and flavoury teas than of those giving thick and coloury liquors, a difference of taste which, if perpetuated, indicates that in future the produce of certain estates and even of some districts may be specially hypothecated to this market, and that the course of manufacture there will in time receive the necessary adjustment to meet its particular requirements.

To sum up what has been said: tea leaf is a variable substance, both by reason of soil and climate, and may be manufactured with primary reference to flavour or to the collective qualities which produce the most acceptable liquor. Within either sphere the market valuation of the product is influenced by two sets of considerations, one of which may conveniently be called "sentimental," the other "utilitarian," and both must receive attention in every effort to improve the value of the tea that is presently being manufactured. Sentiment is mainly responsible for the inordinate valuations frequently placed on "tippy" teas, as compared with intrinsically better quality leaf destitute of tip, and, in the other direction, sentiment leads to the marking down of a tea with open twist as compared with a less palatable and intrinsically inferior leaf manufactured under conditions, fortuitous perhaps, which resulted in its being turned out with a close, firm twist. The utilitarian qualities are those which contribute to the practical usefulness or desirability of the article as a food, and give it value on that ground. No mention has been made under this category of the caffeine, for the reason that, although its presence in tea leaf is undoubtedly one of the principal causes of the extended use of tea as a beverage, such variations in its quantity as occur between one tea and another do not appear to exercise any appreciable influence on market value. The utilitarian qualities most sensibly affecting value are flavour, pungency, fulness and colour of liquor. While practical research must concern itself chiefly with the improvement of teas in respect of these, the element of appearance cannot be left out of account. Tip must be conserved where it exists; red leaf must be excluded in high-class teas by careful plucking, and in the case of common teas, if free plucking be necessary because the grade is low, conditions of manufacture must be so adjusted as to obtain the best appearance consistent with retention of sufficient pungency in the liquor. Withering must be regulated to the degree necessary to give the leaf a mechanical condition such that it will retain the twist during drying. Finally, the sifting and grading of the leaf must be done carefully and yet with expedition, since if it spends too long a time on the sifter it is apt to assume a dull grey appearance that detracts appreciably from its value in the market. Teas low in tannin, common or low country growths, are specially susceptible to this form of deterioration, which, however, a little carelessness in handling may induce even on higher-class leaf, especially the whole-leaf grades.

Within the limitations imposed by appearance there is

still, however, a wide scope for the application of chemical control in the operations of the factory and for a large amount of investigation into the exact nature of the changes that go on during the withering, fermenting, and drying of the leaf, the unravelling of which is already doing something, and will in time do more, to make the course of manufacture regular and the product more uniform in quality than at present. The reactions are complex, and the work of following them out in detail difficult and tedious, but the beginning that has been made gives rise to the hope that more may be done than at present to adjust manufacturing operations in each factory along the lines calculated to enable the highest value to be got from the leaf yielded by the particular soil on the estate.

Beyond that, again, lies the problem of producing artificially the conditions for growing the most flavoury leaf, or of that having the finest liquoring qualities. Spite of the very satisfactory results manuring has given in the way of increased yields, it has not, up to the present, been successful in appreciably enhancing the quality of the leaf grown on any estate, or even to restore quality to its original standard where it had notably deteriorated. That further study will indicate how this may be done there is little doubt: to what extent the methods thereby suggested may be given effect to on a commercial scale will be an economic question to which in course each estate must find its own answer.

THE MANUFACTURE AND PROPERTIES OF SOME STARCH ESTERS.

BY JOHN TRAQUAIR.

The object of this paper is to put on record observations on the chemical properties of a comparatively new class of starch products which are chemically distinct from ordinary soluble starches. These observations are the result of 10 years' research work, a period which synchronises with a considerable development in the methods of starch conversion.

Before dealing with the starch esters, a word or two about starch itself will be permitted. The physical structure of the starch granule has been the subject of much discussion among botanists, and there still appears to be plenty of room for further investigation.

When starch is boiled under ordinary conditions, it does not form a true colloidal solution. The granules become hydrated and swell considerably, and the easily soluble inner amylose attracts water and diffuses out rapidly, while, at the same time, many of the envelopes rupture owing to the osmotic pressure set up. If maize starch, for example, is boiled on a water-bath with 15 or 20 times its weight of water for 15 minutes after swelling the resultant paste appears to be perfectly homogeneous, but if poured into cold water and allowed to stand for a few hours, a whitish mucilaginous mass settles to the bottom. On examining on a microscope, it is seen to consist of the somewhat swollen and ruptured envelopes, the more soluble amylose being in solution. This result can be obtained by treating starch with weak alkaline solutions and various other means, but the foregoing method is perhaps the simplest. The percentage of insoluble and soluble amylose so obtained varies considerably, not only with the different starches, but with the conditions of treatment. We must consider a colloidal starch solution as a heterogeneous system of complex nature, highly sensitive to hydrolytic reagents probably as a result of the amphoteric relations of the constituent units.

During the last two or three years interesting contributions have been made to our knowledge of the chemistry of the hydrolysed starch solution, but the result of this modern investigation has so far tended to emphasise the complexity of the starch granule, and supports the view that starch is a conglutinated substance solidified in the plant from an apparently dissolved state. Starch solutions all show a tendency to revert, that is, to re-form insoluble products, the cause of which may be polymerisation. This reversion occurs not only with ordinary starch when swollen, but with most of the soluble starches and other products of graduated conversion. This

property of reverting from the state of solution causes the starch paste to "set" to an insoluble jelly, and limits the sphere of application. If it were possible to devise a method by which starch could be converted into a physically uniform or homogeneous soluble derivative, giving a permanent solution, there would be considerable scope for its usefulness. It was with this end in view that experiments were first started with starch conversions, and although such permanent solutions have been known for a long time, and are easily obtained by swelling starch in presence of metallic chlorides of hygroscopic qualities, of which the chlorides of zinc, lime, and magnesia, are typical; such solutions are of limited application by reason of the presence of these salts. Ordinary methods of starch conversion, which were all examined, are either simple hydrolysis, generally assisted by the presence of a small proportion of acid, or direct oxidations, or combinations of these two, and are valueless as far as giving a permanent starch solution. The permanent solution represents the true starch colloid, and is evidenced by the evaporation of such solutions to a continuous structureless film, having considerable tensile strength. The continuous films and lustrous threads yielded by the cellulose esters in the interesting series of products which have within recent years risen to considerable industrial importance, first directed attention to the possible value of the corresponding starch esters. Starch and cellulose are closely allied. The difference in their chemical reactions is mainly one of degree.

Starch-nitrate.—This product has been known for many years, and its preparation and properties have been dealt with in various publications, one of which, "Nitrirung von Kohlenhydraten" W. Will and P. Lenze, Berl. Ber., 1898, 68), may be mentioned. The product when thoroughly purified is quite stable, but as it is only of value as an explosive, it need not be further dealt with.

Starch-formate.—Formic acid was first introduced on a commercial scale in 1902, and about the same time the first experiments were made to ascertain its action on starch. Formic acid swells starch in the cold, and if perfectly dry starch is mixed with $1\frac{1}{2}$ to 2 times its weight of 99 per cent. formic acid, it swells to a paste in three minutes. On warming on the water-bath for 15 to 20 minutes a clear, gummy solution is obtained, which can be drawn out into fine threads. On following the process with the microscope, the granules are seen to be only slightly swollen, but are transformed to a soft jelly, as they spread out under a cover glass. The clear solution on pouring into cold water is precipitated as a white flocculent mass. It is plastic at first, but on washing with water forms a granular mass which is easily filtered and dried. The product is a white powder, but lacks the characteristic starch appearance; the yield is about 120 per cent. of the starch used.

The above experiment was repeated, and the clear gummy solution obtained was diluted with an equal volume of 90 per cent. formic acid, and heated for 5 minutes before being poured into cold water. The product now retains its plastic character, and when kneaded with the fingers draws out into very fine threads, which have the appearance and lustre of artificial silk. It dries to a clear gum-like product. The ester is not very stable, and on standing in contact with air or water, slowly decomposes with the elimination of the formic radicle, and a corresponding oxidation of the starch residue. It does not give a blue but a reddish-brown coloration with iodine, and on treatment with dilute alkalis the ester is at once decomposed and the regenerated starch now gives the usual intense blue with iodine.

The product from 30 minutes' treatment at 90° C. shows a fixation of 24 per cent. formic acid on the dry product, which corresponds to a mono-formate on a C_6 formula. If starch is heated at 85° C. with twice its weight of formic acid for 30 hours and the product precipitated with alcohol, washed and dried, it shows a fixation of 55 per cent. formic acid, which corresponds to a tri-formate on a C_6 molecule. This product does not give a blue colour with iodine on saponification, which shows that the starch nucleus has been broken down during the treatment, and that the formate is a derivative of the starch resolution products—dextrine, etc.

Starch-acetate.—Experiments were begun in 1901, and about the same time a paper on the acetylation of soluble starch, by F. Pregl, was published in the Monatsh. für Chemie, 1901, 22 (19), 1049–1066. Soluble starch prepared by Zulkowsky's method was treated at ordinary temperature for 48 hours with 10 times its weight of acetic anhydride containing 1 per cent. sulphuric acid. It yielded a tri-acetate on a C_6 formula. The product is insoluble in alcohol and water, gives no coloration with iodine, and does not reduce Fehling's solution. The yield was 132 per cent. of the starch, and saponification with potassium hydroxide regenerated "soluble starch." Molecular weight determinations were not concordant, but show that the acetyl compound must be of dimensions 8 or 9 times the C_6 formula. A similar product, but soluble in alcohol, is obtained by treatment at higher temperatures (70° to 80° C.) with acetic anhydride containing about 10 per cent. sulphuric acid. The molecular weight is 840, indicating a three-fold formula, and it yields on saponification a product, $(C_6H_{10}O_5)_3N$, which does not give a blue but a red coloration with iodine and is a dextrine. With ordinary starch and acetic anhydride containing 1 per cent. sulphuric acid, acetylation takes place very slowly at ordinary temperatures, but if heated to 90° C. on a water-bath, the starch swells in a few minutes, and goes partly into solution after 30 minutes. If an equal volume of glacial acetic acid is added, a homogeneous solution results in a few minutes. This when poured into a large volume of cold water gives a voluminous granular precipitate which can be washed by decantation. The yield is only 60 per cent., showing that considerable hydrolysis has taken place. The analytical numbers for this product show a large fixation of acetic acid, viz.:—72.5 per cent., which corresponds to a tetra-acetate on a C_6 formula. Reference must also be made to the action of acetic anhydride saturated with hydrochloric acid gas (see Z. H. Skrapup and F. Mentor, Monatsh. für Chemie, 1905, 26, 1415). Also the "dichloroacetic esters" (see Kldiaschwili, J. Russ. Phy. Chem. Ges., through Brewster's Journal, 1905, 41, 688). In each case, however, the reaction simultaneously takes the course of resolution or decomposition, as in the case of acetic anhydride and sulphuric acid. The resulting esters being derivatives of products of decomposition of the original carbohydrate.

Acetic anhydride alone has no action on starch even after two days. At boiling temperature, viz., 140° C., very little acetylation takes place. After 8 hours' treatment, only 2.5 per cent. acetic acid is fixed. This is noteworthy in view of the fact that starch when treated with glacial acetic acid at 120° C. shows acetylation to a much greater extent, e.g., 8 hours' treatment gives a product containing 16 per cent. acetic acid which equals a mono-acetate on a C_6 formula.

Prolonged treatment of starch with 5 times its weight of acetic anhydride at 90° C. gave the following figures:—

Time of treatment.	Acetic acid by saponification.
	Per cent. in dry product.
15 hours	12.1
24	26.2
40	38.5
74	46.8

The products are all insoluble in water and are easily saponified by alkalis with regeneration of the starch. Even after 74 hours the starch granules are little altered.

It is evident that if the starch esters are to be of any value commercially, they must be produced cheaply, and therefore the costly acetic anhydride would require to give way to something more economical.

The action of glacial acetic acid on dry starch was next investigated. When starch is treated with twice its weight of glacial acetic acid and kept at 60° C. for two days, the product is insoluble in cold water and can be washed and dried like ordinary starch. When boiled at 1–10 it gives a paste of the usual consistency, but which shows no tendency to revert on standing, i.e., the solution remains clear for months.

The author (in conjunction with Messrs. Cross and Bevan) has given some figures regarding the acetylation of starch by treatment with glacial acetic acid. (See "Die Niederen Acetyl-derivate von Stärke und Cellulose;" Chemiker Zeitung, 1905, 29, No. 39).

The following more recent observations may be put on record:—Dry starch was treated with glacial acetic acid at 90° C. for the undernoted times, a large excess of acid being used in every case.

Time of treatment.	Acetic acid by saponification.
	Per cent. in dry product.
15 hours	7.2
24 "	10.2
40 "	15.0
50 "	22.8
60 "	28.0
74 "	33.4

At 15 hours the product just ceases to give a blue colour with iodine.

The products are all soluble in water, but insoluble in alcohol. This solubility in cold water distinguishes them from the acetic anhydride derivatives, and is due to the hydrolysing action of the small percentage of water contained in the dry starch and glacial acetic acid. The proportion of acid fixed, increases regularly with the time of treatment, and shows no breaks or steps in the reaction, as would correspond with the molecular proportions involved in the idea of a mono, di, or tri-acetate or the more elaborate series of derivatives which can be theoretically represented on the basis of C_{12} or C_{24} reacting units.

By varying the proportion of acid and the duration of heating, an indefinite number of intermediate products may be obtained. Even at 100° C., with fractional proportions of acetic acid (10 to 50 per cent. of the weight of the starch) some acetylation takes place, the well-washed product showing on saponification the fixation of 2 per cent. to 6 per cent. acetic acid. The products retain the essential characteristics of the original starch, but differ in yielding homogeneous permanent solutions.

The higher homologues of the acetic acid series, viz., propionic and butyric acids, have little action on starch, and as these acids are in no sense commercial products, the investigation was limited to a few preliminary experiments, as was the case with lactic acid.

Technical application.—Formic acid, owing to its vigorous action, evidently would be of considerable value, but its property of swelling the starch granule raised some difficulties. The acid cannot be sprayed directly on to the starch, and although its action in aqueous solution was gone into very thoroughly, satisfactory conversions could not be obtained. Solutions of formic acid of over 40 per cent. strength swells starch in the cold, and even 10 per cent. solutions swell starch at 40° C. in a few hours. Less quantities than this in aqueous solution give products which differ little from ordinary thin starch, i.e., hydrolysis takes place instead of esterification. It was found, however, that a mixture of ordinary methylated spirits and 90 per cent. formic acid did not swell starch at ordinary temperatures. The lowest proportion of alcohol that was effective was one part spirits to two parts formic acid. Experiments were made on a small working scale by mixing starch with 10 to 25 per cent. formic acid diluted in alcohol with fairly successful results. The time of conversion has to be carefully limited to prevent the production of a water soluble product. A very thin boiling product is thus obtained, but on washing with cold water it was found impossible to obtain a neutral product.

The unstable starch-formate decomposed on drying at temperatures as low as 40° C., and although the wet product was carefully neutralised, then filter-pressed and dried slowly, the dry product was distinctly acid, showing frequently as much as 0.5 per cent. free formic acid. If the product was boiled with water as usual, the acid

solution neutralised, and the boiling continued for 10 to 15 minutes, a further production of acid ensued, owing to the decomposition of the starch-formate by HOH hydrolysis. These properties naturally limited the usefulness of this conversion, as a neutral product is essential for the majority of industrial purposes.

Acetic acid in aqueous solution has little action on starch, and no useful results were obtained. Glacial acetic acid has been found to be most suitable, and gives on the whole the best results from a technical point of view. It is necessary to use as nearly anhydrous materials as possible, and therefore the starch requires to be dried, so that it contains not more than 3 or 4 per cent. moisture. For commercial purposes, the reaction must be limited to a product insoluble in cold water, so that the excess of acid can be removed by washing by decantation. With excess of acid at 90° C. the limit is about 8 hours' treatment, and at 120° C. 2 to 3 hours. The water insoluble product in each case showing a fixation of 4 to 5 per cent. acetic acid. The product, when swelled with 5 or 6 times its weight of water, gives a clear viscous solution which is permanent, and on pouring out on a glass plate dries to a clear continuous film.

Manufacture.—Owing to these laboratory experiments being satisfactory, a small plant was erected to test the reaction on a manufacturing scale. Results of many experiments showed that to obtain the maximum conversion, the starch must be as dry as possible, and an equal weight of acid used. This gives a fluid mixture which can be boiled slowly. Treatment is continued for 2 or 3 hours, and the product washed out carefully with cold water. With limited quantities of acid a series of products quite suitable for most industrial purposes were obtained. The only condition seriously affected by decreasing the quantity of acid is the keeping property of the solution, but this can be favourably modified by increasing the time of reaction.

Technical development.—The process was patented in 1902 in Britain and several other countries, and in Germany a patent was granted after considerable opposition on the part of some local makers of "soluble starch."

The word "Feculose" (from "*fecula*," Latin for starch) was registered, and by this term the various commercial starch esters are now designated. A large plant was erected in which the experience gained in the earlier stages was embodied, and although the industrial process has necessitated considerable study, and devising of special converters for carrying out the treatment of dry starch with glacial acetic acid, at temperatures of at least 120° C., still the engineering difficulties were overcome, and the plant does not call for any special description.

The development of the process was mainly on the lines of limiting the quantity of acid, and perfecting the recovery, but it was found that 10 per cent. glacial acetic acid on the dry starch was the minimum quantity which would give useful products. The acetylation can be much accelerated by using small quantities of mineral acids along with the glacial acetic acid, but under these conditions the conversion requires to be very carefully controlled, as water soluble products are very apt to result. Mixtures of glacial acetic acid and formic acid can also be used in varying proportions to give special results.

The acetylated starch as it comes from the converter contains from 4 to 5 per cent. uncombined acetic acid, which in most cases has to be removed before the product is in a marketable form. The cheapest method of doing this might be to neutralise directly with a suitable alkali, but this would mean the formation of a considerable quantity of salts, the presence of which would be objectionable for many purposes. The best method is to wash by decantation with cold water. It is therefore very necessary that the reaction should be limited to a product which is insoluble in cold water. If the reversion is carried too far, not only does the loss become very serious, but the acetylated starch granules seem to hydrate in cold water, and can only be dried to a gummy mass. Under proper conditions, the acetylated starch can be washed and dried like ordinary starch.

It has been found that the various commercial starches, e.g., potato, maize, rice, tapioca, sago, and wheat, give in some degree a product with distinct physical properties.

The larger granulated starches are preferred owing to the ease with which they are washed free of acid, but all are used more or less.

It is evident that by varying the starch base operated on, the reacting acids, the time and temperature of treatment, a range of products of endless variety can be obtained. No other reaction presents such a field of possibilities, and this is a strong point in favour of this type of reaction. It is possible to produce varieties of acetylated starch giving solutions of varying consistencies from a thick jelly at 1—10 to a thin solution at 5—10. Also types giving soft lustrous films on glass, and others stiff dull films.

Properties.—Feculose differs little in appearance from ordinary starch, and on boiling with water it gives a clear homogeneous solution which does not "set" or revert on standing a few hours. The films obtained by allowing a little of the solution to dry on a clean glass plate are clear and flexible, and equal to those obtained from the finest gelatin. The solution does not reduce Fehling's solution, and gives the usual blue with iodine. It is precipitated out by alcohol or strong solutions of certain salts similar to ordinary soluble starch, and also readily reacts with diastase under the usual conditions.

The acetylated starch (or Feculose) reacts with most chemical reagents much more easily than ordinary starch, and therefore lends itself to further modification. The washed feculose is neutral or slightly acid, and saponification with sodium hydroxide shows that only from 1—4 per cent. acetic acid is fixed on a C_6 molecule. The effect of this on the properties of the solution is out of all proportion to the fraction of the starch aggregate which evidently takes part in the reaction. It can only be assumed that the small proportion of reacting molecules is capable, on hydration, of radically influencing the whole complex, or, that some constitutional changes in the starch take place simultaneously with a fixation of acetyl groups.

Uses.—The uses of feculose can only be dealt with briefly, but it is evident that it is an ideal substitute for gelatin and vegetable gums, and has been applied successfully in many directions. It has obvious applications as a special textile finish, in which its properties as a true colloid enable it to confer lustre, and also to penetrate and give substance and "handle" to textiles in the form of yarn or cloth. The clear filming property is particularly apparent on bright colours, such as reds and yellows, where it seems to increase the intensity of the colours. On light cottons, where no softeners are used, feculose at 1 lb. per gallon gives equal results to dextrin at 3 or 4 lb. per gallon. It is also used along with ordinary starch to give flexibility and cleanness to the finish, leaving the proportion of starch to be varied according to the stiffness required. It gives excellent results for linen dressing, and in lace dressing it gives the desired springy finish, while it is the only starch product which will not dull the lustre of mercerised cotton.

Dyeing and French cleaning is another branch where its special qualities are appreciated. (See Farrell, J. Soc. Dyers and Col., Dec., 1908.)

In silk finishing little sizing materials are used, but the brilliant films given by feculose make it suitable for this class of work.

Confectionery.—Feculose is also employed in making ju-jubes and other sweets, and the fact that it can be cooked up with sugar and glucose to any "steam" temperature, opens a wide field of possibilities for its application, especially when the limitations of gum and gelatin in this direction are known and recognised.

Paper manufacture.—The use of Feculose in this particular industry has received a great deal of study, but would require to be dealt with in a special paper. It is perhaps sufficient to say that, in paper-coating, feculose gives excellent results as a size in place of "chromo" glue or casein. The surface produced has excellent printing qualities owing to its unique ink affinity. In fact, technically, Feculose might be described as a non-nitrogenous gelatin. A permanent solution of Feculose can be obtained by means of variations of the original processes, and modifications introduced by subsidiary treatments, thus enabling it to fulfil a very large range of technical requirements.

It is perhaps interesting to note that these products, representing as they do the latest developments in starch conversions, have been worked out and brought to a manufacturing stage by one of the oldest starch firms in the country.

In conclusion I have to thank the proprietors of "Feculose," Messrs. William Wotherspoon, Ltd., Gifford Starch Works, Paisley, for permission to publish the foregoing particulars, and Mr. C. E. Cross, London, for assistance and advice in preparing this paper.

Yorkshire Section.

Meeting held at Queen's Hotel, Leeds, on Monday, February 22nd, 1909.

PROF. W. M. GARDNER IN THE CHAIR.

A METHOD FOR THE ESTIMATION OF NITROGEN IN ORGANIC SUBSTANCES; AND IN PARTICULAR, FOR THE DETERMINATION OF HIDE-SUBSTANCE IN LEATHERS AND OF DISSOLVED HIDE-SUBSTANCE IN THE SOAK LIQUORS AND LIME LIQUORS OF THE LEATHER FACTORY.

BY HUGH GARNER BENNETT, M.Sc.

The Kjeldahl process of nitrogen estimation is open to several sources of error, and numerous forms of apparatus have been devised to carry it out with the maximum convenience, accuracy, and speed. The great advantage of the process now suggested is that no such apparatus is at all necessary, the whole operation being conducted in one flask.

It is some years since the reaction between ammonia and formaldehyde to form hexamethylenetetramine was first employed as a means of estimating the latter, but it is only recently that the same reaction has been utilised for the estimation of ammonia. It has been shown, however, that if a formaldehyde solution be added to an ammonium salt, the formation of hexamethylenetetramine takes place as usual, and the acid combined with the ammonia remains as free acid, and can be titrated (Ronchèse, J. Pharm. Chim., 1907 (VI.), 25, 611—617). It is now suggested, therefore, that this process of ammonia estimation should be combined with the Kjeldahl method of digesting with sulphuric acid, for the estimation of nitrogen in organic substances.

The substance under examination is digested as usual with sulphuric acid until the liquor is clear, and the excess of acid carefully neutralised by adding a solution of caustic soda until a pink colour is obtained with phenolphthalein. A neutral solution of formaldehyde is then added, liberating the sulphuric acid present as ammonium sulphate, according the equation:—

Hexamethylenetetramine is quite neutral to phenolphthalein and the liberated sulphuric acid is then titrated with $N/10$ sodium hydroxide solution until the pink colour returns. From the amount of $N/10$ alkali used, the amount of ammonia originally present as ammonium sulphate, and hence also the amount of nitrogen present in the substance under examination can easily be determined.

This mode of procedure has been found very convenient for the estimation of hide-substance in leathers, one of the most important determinations in leather analysis. From 0.4 to 0.5 gm. of leather is accurately weighed out into a Jena flask of about 500 c.c. capacity and digested over a small flame with 15 c.c. of concentrated sulphuric acid until clear. The liquor in the flask is then carefully neutralised to phenolphthalein; a 50 per cent. solution of soda is used until the solution is nearly neutral, and the neutralisation then completed with $N/10$ sodium hydroxide. The formaldehyde solution (25 c.c. of about 40 per cent. strength) is now added to the flask, and after

mixing well the liquor is titrated with $N/10$ caustic soda until a permanent pink is obtained. Each c.c. of $N/10$ alkali required corresponds to 0.0017 gm. of ammonia or 0.0014 gm. of nitrogen, or 0.00786 gm. of hide-substance, as hide-substance contains 17.8 per cent. of nitrogen. Commercial solutions of formaldehyde are usually slightly acid, and of course must be made neutral before adding to the flask. This may be done by neutralising to phenolphthalein with standard caustic soda, or by shaking the solution up with barium carbonate and allowing it to stand overnight. The following results were obtained with leathers treated with this process and with the ordinary Kjeldahl process:—

No. of leather sample employed.	Percentage of nitrogen found.	
	Formaldehyde method.	Kjeldahl method.
1.....	12.20	12.20
2.....	12.50	12.48
3.....	12.20	12.20
4.....	14.70	14.68
5.....	14.00	14.00
6.....	12.08	12.12
7.....	12.21	12.19
8.....	11.64	11.61
9.....	13.25	13.24
10.....	11.67	11.65
11.....	12.40	12.40

In applying the process for the estimation of dissolved hide-substance in soak liquors and lime liquors, 100 c.c. of the filtered liquor is pipetted into the Jena flask, made distinctly acid with sulphuric acid, evaporated to small bulk, and then digested with concentrated sulphuric acid and titrated as before. The following results have been obtained with a series of tannery lime liquors:—

Liquor.	Mgrms. of nitrogen per 100 c.c. liquor.	
	Formaldehyde method.	Kjeldahl method.
1.....	15.68	15.68
2.....	42.00	41.90
3.....	45.36	45.29
4.....	19.88	19.80
5.....	50.96	50.96
6.....	12.60	12.51
7.....	42.00	41.85

The amount of hide-substance which has gone into solution is usually calculated on the assumption that 17.8 grms. of nitrogen correspond to 100 parts of dissolved hide-substance.

It is of course conceivable that in certain cases some complication may arise which will prevent the successful use of this method. One such case has come under the author's notice. In determining the nitrogenous matter in silk by both Kjeldahl and formaldehyde methods, the following results were obtained:—

Sample.	Percentage of nitrogen.	
	Formaldehyde method.	Kjeldahl method.
Black silk.....	(1) 7.4	(1) 8.7
	(2) 7.4	(2) 8.6
White silk.....	(1) 7.1	(1) 8.3
	(2) 7.1	(2) 8.2

The analyses (1) and (2) were duplicate determinations, and always showed concordance, but the two methods yield different results. For some reason a constant error is introduced, but the cause is not very obvious. A possible explanation is that amine sulphates are formed instead of ammonium sulphate, and that the amine is distilled off with ammonia in the ordinary process and neutralises some of the standard acid, but that it is not

acted upon or estimated in the formaldehyde process. Longer digestion with sulphuric acid might overcome this difficulty.

The author's thanks are due to Mr. Arnold Seymour Jones for his assistance in carrying out the experimental work recorded above.

DISCUSSION.

Prof. PROCTER said the method would probably be very useful to technical analysts because many experiments could be made in a short time with it, and the results appeared to be as accurate as by the direct method.

Prof. W. M. GARDNER asked if the method could be used with wool, artificial fertilisers, and other technical products.

Mr. H. G. BENNETT, in reply, said that the method had only been tried with lime liquors, leather, and silk. The great advantage of the method was not so much the saving of time as the fact that no special apparatus was required for carrying it out.

THE COMMERCIAL CONTROL OF TANNERY LIME LIQUORS.

BY HUGH GARNER BENNETT, M.Sc.

The lime liquors used for the depilation of hides and skins in leather manufacture are always used for several packs of goods, and although a new lime liquor is an almost completely sterile medium, the solvent effect it exerts on the various proteid matters which enter it causes a gradual increase in the amount of organic matter which is in solution. In this way it is made possible for certain bacteria to thrive, and these also assist in dissolving further quantities of both keratinous and gelatinous matter. When such liquors therefore are repeatedly used, there is not only a rapid accumulation of hydrolytic and putrefactive decomposition products of the proteids, but also an almost proportionate multiplication of the fermentive organisms; and it is evident that if this repeated use be continued indefinitely, the liquor will continue to unhair, but by virtue of its bacterial rather than its chemical activity.

In the manufacture of many leathers it is important that this bacterial action should not be taken too far, and it is in all cases desirable to know how far it is necessary, and to ascertain whether any given lime liquor is likely to produce the desired effect. Many processes have therefore been suggested for determining the age and degree of "mellowness" of an old lime liquor. The most obvious way is to determine the amount of dissolved hide substance in the liquor by the estimation of nitrogen by Kjeldahl's method, but this is far too tedious for the control of the ordinary lime yard, and is resorted to only in special cases. The estimation of the free ammonia has also been taken to indicate the age and character of such lime liquors, partly under the impression that this ammonia had a powerful unhairing action, and partly with the idea that its quantity was at any rate roughly proportional to the total dissolved hide substance and also to the bacterial activity. The accurate estimation of ammonia in a lime liquor, however, is a matter of some difficulty, and usually involves a somewhat complicated apparatus. It has recently been stated, moreover, that ammonia in old limes does not give the depilatory and solvent effect so long attributed to it, and that the effect of old limes is due almost entirely to bacterial action. The estimation of peptone acids formed by the action of formaldehyde after the removal of the lime with zinc sulphate, has recently been proposed as a measure of the dissolved hide substance, but its author, as well as the present writer, found that the results it yields are by no means strictly proportionate to the nitrogen determined by Kjeldahl's method.

The method now suggested has been employed by the author for some years, but because of its somewhat empirical nature and scientific imperfections, he has not thought it desirable to publish it. The present paper is due to the fact that it was found to be more accurate than was expected, and also because it was found to be exceedingly useful and convenient for control work. The decomposition of the proteid matters of the skin results in formation of peptones, the calcium salts of amido acids

and other weak acids, amines and a certain quantity of ammonia, all of which are of a weakly basic nature. The method of determining these is simply to titrate 25 c.c. of the filtered lime liquor with *N*/10 hydrochloric acid in the presence of phenolphthalein and methyl orange, the former being sensitive only to the strong bases (*e.g.*, lime), whilst the latter is also sensitive to the weak bases mentioned above. The 25 c.c. liquor are placed in a white porcelain basin and diluted somewhat with distilled water. Phenolphthalein (3 drops of a 1 per cent. solution) is added, and the *N*/10 acid slowly run in with constant stirring until the pink colour just disappears; the volume of acid used being then noted. Methyl orange (2 drops of a 0.1 per cent. solution) is now added to the basin, and the addition of standard acid continued until the indicator first distinctly changes towards red; the volume of acid used is again noted. The difference between the two readings represents the weak bases formed by the decomposition of the hide, and is proportional to the "dissolved hide substance" and to the bacterial activity and "mellowness" of the lime liquor. It is of course known that the end-point in titrating ammonia in the presence of phenolphthalein is not very accurate, but the quantity of ammonia in ordinary lime liquors is usually small, and forms a very meagre proportion of the nitrogenous decomposition products, and hence the error caused by its presence is not sufficient to impair seriously the accuracy of the method. The end-point with methyl orange, on the other hand, is not perfectly sharp, but can usually be confirmed very closely by a duplicate titration. The following results were obtained with a series of lime liquors, using the above method, and also estimating nitrogen by Kjeldahl's method and by the formaldehyde method recently suggested by the author.

(1) Titration difference for 25 c.c. lime liquor using <i>N</i> /10 hydrochloric acid.	(2) Ammonia obtained by Kjeldahl method; equivalent in <i>N</i> /10 sodium hydroxide.	(3) Formaldehyde method, no. of c.c. <i>N</i> /10 sodium hydroxide required.	Ratio of column (3) to column (1).
4.10	2.80	2.80	0.68
5.37	3.50	3.55	0.68
11.0	7.45	7.50	0.68
11.75	8.05	8.10	0.68
13.5	9.05	9.10	0.67

The relative concordance between the various methods with lime liquors so widely varying in age was greater than the author expected, and at any rate justifies the process now suggested for control work. The above results were obtained with lime liquors from a large leather factory where a regular system of liming is employed, and it may be taken therefore that for these liquors, 1 c.c. titration difference (with *N*/10 hydrochloric acid and 25 c.c. liquor) corresponds to 0.0053 gm. of dissolved hide substance. The author has received about 30 other comparative analyses of lime liquors from the factory, all of which confirm this factor. The most discrepant results occur with the comparatively fresh limes, in which the titration difference is small; a slight error in the end point causing a comparatively large percentage error.

It is possible, of course, that other tanyards with other systems of liming may find a different factor, but the probability is that it will be constant for any regular system. In cases where a small amount of sulphide of sodium is regularly used to assist depilation, a constant error will be introduced in the factor, depending upon the amount of sulphide. The titration must also in this case be conducted with considerable dilution; the sodium hydrate and sulphhydrate formed from the sulphide being then accurately alkaline and neutral respectively to phenolphthalein, whilst both are alkaline to methyl orange. In cases of quick depilation with considerable quantities of sodium sulphide, the most useful figure will be the total alkalinity as determined with methyl orange. The author desires to thank Mr. Arnold Seymour Jones for his

assistance in carrying out the analytical work here recorded.

DISCUSSION.

Prof. H. R. PROCTER said he had previously used the method suggested, without, however, working it out so carefully as the author had done. The method was extremely easy and gave fairly approximate results. The difficulty in the end-point could be overcome. In addition to the difference between the titrations, the total titration with phenolphthalein was of significance. Saturated lime liquors were usually used. These are about one-twentieth normal, so that if the liquors consumed more acid than was equivalent to this, the excess must be put down to ammonia or caustic soda. The latter was often present in lime liquors owing either to direct additions of sulphides or carbonates or to its removal from skins treated with these materials.

Mr. C. E. PARKER said that heavy loss was without doubt going on in different tanneries through the dissolving of hide substance in the lime liquors used. Those tanners who took proper steps to prevent this were obtaining valuable results, and therefore such a method as proposed, combining rapidity and accuracy, would be of great service in locating such losses.

Mr. J. T. WOOD said that he had been in the habit of titrating 10 c.c. of filtered lime liquor with decinormal hydrochloric acid using phenolphthalein as indicator. The liquors gradually increased in alkalinity, and when they required more than a certain number of c.c. of the acid they were no longer used. No doubt many tanners still guessed the condition of the liquors, but the method of the paper could be applied with little extra trouble than the one he used and with valuable results.

Mr. A. SEYMOUR-JONES said the method was useful for showing the exact rate at which hide substance was lost. This was of importance in the case of cotton-spinning leathers. Here the object was to get rid of a certain amount of hide-substance and to obtain a softer product, instead of getting the materials as hard and heavy as possible, as in the case of sole leather. He had used the method since Christmas with good results. Sound leather was made in the lime yard, and if this part of the work was properly done it was easy for anyone to do the rest.

THE DETECTION OF SULPHITE-CELLULOSE LIQUORS IN TANNING EXTRACTS.

BY PROF. H. R. PROCTER AND S. HIRST.

In the manufacture of paper pulp by the bisulphite process, the coniferous woods are digested under pressure with a solution of calcium bisulphite, which dissolves the ligneous constituents, leaving a comparatively pure cellulose. Enormous quantities of the used sulphite liquors, containing large amounts of dissolved vegetable matter, are run into rivers, or into the sea. It has been found, however, that after suitable decolorisation and concentration in the vacuum pan, these liquors will yield an extract very similar in appearance to oakwood, and which when analysed by the I.A.L.T.C. official hide-powder method, will show about 25 per cent. of tanning matter or substances absorbed by hide. Such a purified extract has been put upon the market under the name of "Pinewood" or "Fichtenholz" extract. If attempts are made to tan with this extract alone, it is difficult, if not impossible, to obtain a product which deserves the name of leather, the surface being apparently tanned, while the interior remains raw and unaltered, and the hide dries horny and usually of unsatisfactory colour. If, however, the hide be in the first instance partially tanned with some ordinary tanning material, or if some other tanning extract be used in conjunction with the pinewood extract, leathers are produced similar in appearance to those of ordinary tannages, as the pinewood extract appears capable of absorption, giving firmness and weight, although it probably contains no bodies analogous to the ordinary tannins. It may therefore ultimately become a useful addition to the tanner's resources, but while

experiments with it were at first apparently successful as a weighting and solidifying tan, some constituent appeared to accumulate in the liquors which led ultimately to the production of brittle or tender leather. Whether this was due to mis-management, the writers cannot at the moment say, but so far as they are aware, but little of the extract has been sold to tanners under its own name. It is, however, obviously a tempting material for the extract manufacturer, as considerable quantities can be added to tanning extracts without altering their appearance, and it shows a good percentage of tanning strength by the ordinary method of analysis. It is therefore important in the interests of the tanner that means should be discovered for the detection, and if possible, the estimation of pinewood extract in mixture, and a good deal of time has been devoted by the writers to the attempt to discover a satisfactory qualitative colour reaction, and it has been found that the following modification of the ordinary test for lignine with aniline and hydrochloric acid is very delicate and quite satisfactory.

To 5 c.c. of the extract solution, which should be of about the ordinary strength employed for analysis, 0.5 c.c. of aniline is added, and the whole is well shaken, and 2 c.c. of concentrated hydrochloric acid is then added to the mixture. With all ordinary extracts this has the effect of immediately clearing the turbidity caused by the aniline, and a perfectly transparent solution results, but where pinewood extract is present, even in comparatively small quantity, a precipitate is rapidly produced which gradually rises to the top of the liquid. Heating is not necessary, and on the whole not desirable, though it sometimes increases the rapidity of the separation of precipitate. The reaction, however, is immediate, and any slight turbidity which arises after considerable standing should be disregarded, as it sometimes occurs in the case of unaltered extracts, possibly from minute traces of ligneous matter. It is possible that this method may be developed into a quantitative form, but this has not yet been attempted by the authors.

It was also found that the "tanning substance" of the pinewood, while it was estimated as tannin by the ordinary hide-powder process, was only to a very small extent capable of reducing permanganate in the Löwenthal method, and therefore gave almost negative results in tannin, a pinewood extract showing about 25 per cent. of matters absorbed by hide being only equivalent by the Löwenthal method to about 1 per cent. of gallotannic acid. This property of low oxidisability is not shared to nearly an equivalent extent by any ordinary tanning material, and therefore pinewood extract can be detected, and even estimated approximately if present in considerable quantity, by comparison of the gravimetric and Löwenthal results.

The following table gives the values as compared to gallic acid of the tanning matters absorbed by hide-powder from 3 samples of sulphite cellulose extract, and average values for those of oakwood and chestnut extracts, with which it is most likely to be mixed.

Extract.	Gallie acid value of 1 gm. tannin.
" Fichtenholz " I	0.129
" " II	0.090
" " III	0.137
" " average	0.119
Chestnut	0.604
Oakwood	0.527

It was hoped by the authors to develop on this basis an approximate quantitative method; and arithmetically, if a be the gallic acid value of the genuine extract, b the (lower) value for "pinewood," and c that experimentally found for an unknown mixture, $\frac{a-c}{a-b}$ should be the fraction of the total "tannin" found by ordinary gravimetric analysis which is due to "pinewood." Not only, however, are the required constants usually unknown, and subject to considerable variation in

different extracts made from the same material, but even when the method is applied to known mixtures, the results are only approximate, and usually indicate less than the actual amount of "pinewood" really present, suggesting that the absorption of one of these matters by the hide is affected by the presence of the other. This point is still under investigation, and may lead to interesting results.

DISCUSSION.

Mr. H. G. BENNETT said that the facts just given showed that pinewood extract contained none of those bodies ordinarily known as "tannins." It contained, however, some substance absorbed by hide-powder. It had been suggested as profitable for weighting sole leather in drum or vat. The Löwenthal method showed the absence of true tannins.

Mr. C. E. PARKER asked how quickly the matter absorbed from pinewood extracts would wash out from leather.

Mr. H. G. BENNETT replied that it would probably wash out at the same rate as the ordinary weighting extracts, but possibly less readily.

Prof. A. SMITHells remarked that if the substance dissolved out of the pinewood by bisulphite was of an aldehydic nature, it might be expected to have some degree of tanning power.

Prof. H. R. PROCTER said he had tested for furfural and other aldehydes with negative results, but proved the presence of lignin by the aniline test.

Mr. J. E. BEDFORD suggested that a stipulation should be introduced into contracts made by tanners prohibiting the addition of pinewood extracts to tanning extracts.

Mr. C. E. PARKER welcomed the suggestion and said he would bring it before the United Board of the Tanners' Federations. Some such clause should be introduced, since the I.A.L.T.C. method of analysis did not detect the presence of pinewood extract.

THE USE OF THE LOEWENTHAL METHOD IN •THE CONTROL OF TANNERY LIQUORS.

BY PROF. H. R. PROCTER AND S. HIRST.

For the purposes of a recent paper on "The Detection of Sulphite Cellulose Liquors" (see page 293), factors were determined for the calculation of Löwenthal results to equivalent values of "tanning matters" as estimated gravimetrically, for a considerable variety of extracts and other tanning materials. The Löwenthal method is fully described in Procter's "Leather Industries Laboratory Book," and details need not be repeated, but as a large number of titrations had to be made, some mechanical improvements were adopted which greatly facilitated the operation. Self-filling burettes of the simple form shown in the figure were used both for permanganate and indigo, and the titration was carried out in a beaker of about 1 litre capacity fitted with a spindle carrying two small screw propellers, made either of stiff celluloid or of brass coated with celluloid varnish, and driven by a small turbine or electric motor. For comparison, a similar beaker filled with an already titrated liquid was placed in a similar light and beside that in use. Under these conditions titrations were very rapidly made and with almost absolute concordance, and the systematic use of the method for control of the tanning strength of liquors naturally suggested itself. Of course there is nothing new in such an idea, but no carefully thought-out and systematic mode of work has hitherto been published. For practical purposes the method requires to be as simple and rapid as is compatible with concordant results, and as tanning materials are now almost universally bought by the I.A.L.T.C. method of analysis, it is important that the figures should be comparable with this method, and on this account detannisation by chromed hide-powder was

preferred to that by gelatine, although the latter is theoretically more exact, being less affected by astringent non-tanning matters, such as gallic acid.

Since the actual amount of permanganate used varies somewhat with the operator and the details of titration, the usual method of calculating the results of a Löwenthal analysis is by direct comparison with a supposed pure solution of gallotannic acid, but as actually pure gallotannic acid cannot be obtained, allowances have to be made for an assumed but unascertained amount of impurity; commercial gallotannic acid of the best quality usually reducing more permanganate than the theoretically pure substance. Gallic acid, being crystallisable, is readily obtained in a pure form, and is oxidised by permanganate in a similar way to gallotannic acid, 1 gram. of crystallised gallic acid reducing approximately the same amount of permanganate as 1.34 grains. of the portion of the purest obtainable gallotannic acid absorbed by chromed hide-powder. There is, however, little advantage in calculating in this way, since few, if any, of the tanning materials in use contain solely gallotannic acid, and the different tannins are well known to reduce permanganate in somewhat varied proportions. It is therefore more practical and convenient to state the results of experiment in terms of gallic acid, and it is easy to obtain a factor by which the latter can be approximately calculated to any tannin as determined by the hide-powder method.

The following solutions are employed:—(1) Pure air-dried gallic acid, 0.1 gram. per 100 c.c. freshly made. (2) Purest indigo-carmine, 5 grains. per litre, with 50 grains. of concentrated sulphuric acid, 25 c.c. being used for each determination. A solution of 1 gram. "indigo pure B.A.S.F." in 25 c.c. concentrated sulphuric acid diluted to 1 litre with 25 c.c. added sulphuric acid, may also be employed. These solutions both keep well. 25 c.c. of either must require 25–30 c.c. of permanganate for oxidation, or a larger measured volume must be used. (3) Permanganate of potash solution, 0.5 gram. per litre, made by the dilution of a 5 gram. per litre solution at frequent intervals, as very weak solutions do not keep satisfactorily.

The liquor to be tested must be so diluted that 5 c.c. will not consume more than two-thirds of the permanganate required by the 25 c.c. of indigo always used, and thus the complete titration can always be made with the contents of a 50 c.c. burette. Sufficiently accurate readings can be made from the upper edges of the liquids without the use of a float. It is important that the stirring turbine should run with fair uniformity (if hand-stirring is relied on, it must be constant and efficient), and the dropping should be at a regular rate. Generally this may be as fast as separate drops can be counted, until the original blue colour has become yellow-green, after which permanganate is added drop by drop to complete discharge of the blue. It is well occasionally to time the titration so as to ensure constant work. The titration is even more easy by good artificial light diffused by ground glass or tissue paper than by daylight, the removal of the last trace of blue being shown by a very marked brightening of colour; but as the end-points are not quite identical, all the titrations for any single analysis must be done in the same light.

The tanning matter is of course indicated by the difference of titration of the original and detannised liquor, but as neither dissolved salts or traces of hide-substance have any appreciable effect on the titration, the detannisation may be much simpler than that required for actual gravimetric analysis. Washing of hide-powder after tanning is quite needless, the powder being merely bromed, pressed, weighed, and the requisite water added; and 6 c.c. of the detannised liquor counted as five; but a still greater simplification may be effected by the use of a soft Paessler's dry "lightly chromed" powder, or by the use of freshly air-dried chrome leather machine shavings as suggested by Kopecky. About 7 grains. of the dry powder and a little kaolin should be added to 100 c.c. of the diluted liquor, well mixed by hand shaking, and shaken for 10–15 minutes in the machine. The moisture of such quantity of a powder only amounts at most to 1 gram. even if the whole of it acts as water of dilution, which is very doubtful, and can at most cause an error of 1/100th of

the total tannin in the diluted liquor; and as the analysis is only for comparative purposes, and the error, such as it is, is a constant one, it may well be neglected. The detannised liquor is filtered till clear through paper, and 5 c.c. is with 25 c.c. of indigo twice titrated. If the work is systematic, the amount of dilution required for each class of liquor will be known sufficiently nearly; if not, a simple titration of the undetannised liquor will be a sufficient guide, and for this purpose it is better to dilute too much than too little. The final result is of course divided by the number of c.c. of original liquor taken per litre and multiplied by 1000. It is best to use distilled water for this dilution, but any good tap water will do for titration. Whether the liquor should be filtered clear before or after dilution, or not at all, is a matter for consideration; but if not, any suspended solids, such as those of quebracho, or the catechin of gambier, will largely dissolve on dilution, and be estimated as tannin, which is not necessarily an error, since to some extent the same thing happens as liquors become exhausted in the tannery. It is not necessary to filter the liquor for detannisation, and a good compromise would be to filter only the portion of diluted liquor required for titration, through any good quantitative paper. The systematic method of work would then be that the liquors to be tested would be brought to the laboratory first thing in the morning, and there diluted as required. 100 c.c. of each of the diluted liquors would be placed in shaking bottles with the requisite dry chromed hide-powder and kaolin and shaken by hand till well mixed; and a portion of each of the diluted liquors filtered, the first turbid portions being rejected. The operator would then shake the bottles in the machine, and set their contents to filter while he proceeded with the titrations of the diluted liquors.

The first step is to make fresh the weak permanganate by diluting 100 c.c. of 5 gram. per litre strength to 1 litre, as the strong solution keeps well while the weak soon alters, and to shake this very thoroughly in the stock-bottle to ensure complete mixture. 25 c.c. of the indigo is then twice titrated alone, and the titration repeated with 5 c.c. of the freshly-made gallic acid solution, 0.1 gram. in 100 c.c. The sum of the differences between these will give the permanganate value of 0.01 gram. of gallic acid, which will be practically constant from day to day with careful work and a single operator, and perhaps need not be every day repeated.

The titration of 5 c.c. of the diluted liquors is now similarly performed, and then that of 5 c.c. of the corresponding detannised portions, the titrations always being done in duplicate to check possible errors, and the sum of the two results taken. If now the result of the detannised liquor be deducted from that of the original diluted liquor the quantities of permanganate consumed by indigo will cancel each other, and the result will be the permanganate value of the tannin of 10 c.c. of (diluted) liquor; and

Permanganate consumed by gallic acid	permanganate consumed by liquor	1 gram. per litre gallic acid	gram. per litre of tannin in liquor expressed as gallic acid.
--	---------------------------------------	-------------------------------------	--

If for 1 gram. per litre, the weight of the actual tannin corresponding to 1 gram. of gallic acid be substituted, the strength of the diluted liquor will be obtained directly in gram. per litre in "tanning matter"; and from this by simple multiplication by the dilution, that of the original liquor. 1.34 in place of 1 will give the strength in terms of gallotannic acid; 1.76 is the average of about 30 analyses of all the common tanning materials, and Table I. gives factors averaged from several analyses of each of the more important.

If, however, it be desired to obtain an actual experimental figure for the liquors of the particular tannery, or for any particular tanning material, this is easily done by combining the Löwenthal with an ordinary gravimetric analysis of an average liquor by the shake method; the actual "total soluble" and "non-tannin" solutions being used for the titration. Then the result in gram. per litre found gravimetrically, divided by the "gallic acid value" by Löwenthal, will give the factor required, *viz.*, the weight of the tannin corresponding to 1 gram. of gallic acid.

The Löwenthal method as applied to liquors not only has the advantage over the gravimetric method of much greater rapidity, but is probably of greater relative accuracy with weak liquors, as no concentration is required: the following figures obtained independently for a set of liquors by two different students illustrating the sort of concordance to be expected. The factor used was $\frac{1}{2}$ or 1.66, which was the average of several determinations of the materials used.

The method is one which can easily be mastered by any intelligent youth without much chemical knowledge, and if it were combined at the same time with lime-water determinations of acidity, would give information as to variations in the working of a yard which could hardly fail to be valuable commercially. It is, however, only to be recommended for continuous and systematic work, and its use for occasional analyses is more troublesome than the ordinary gravimetric method.

The method is equally adapted to the control of spent tans, since very weak liquors can be as accurately determined as strong ones, 10 c.c., or more, if necessary, being used for each titration instead of 5, so that a sufficient quantity of water can be used for complete exhaustion. The material can be dried, ground fine, and extracted in the Procter extractor in the usual way: but for comparative tests it would often be sufficient to boil up 5 lb. of the wet material as it comes from the leaches with a gallon of water for half an hour, allow to stand overnight, and draw off the liquor, making up to one gallon, if necessary, by the addition of enough water to the material to supply the loss by evaporation, and Löwenthal the liquor. Though this would give no precise information as to the exact amount of tannin left in the material, it would at once detect any variations in the completeness of the leaching, and if compared to an occasional more complete analysis, would probably give all necessary information.

As regards the theoretical significance of the Löwenthal results, it is interesting to note that the table of factors given, partially bears out the statement formerly made that catechol tannins reduce materially less permanganate than gallotannic acid or pyrogallol tans. 1 gm. of the purest gallotannic acid is only equal in reducing power to 0.742 gm. of gallic acid, and in all cases the reducing power of the "tanning matters" absorbed by hide-powder is still lower, the highest being that of sumach, of which in one sample 1 gm. had equal reducing power to 0.680 gm. gallic acid: while the lowest are the tannins of coniferous barks, ranging from about 0.4 for spruce bark to 0.5 for larch and hemlock. Chestnut extracts average about 0.6. Oakwoods and myrobalans range from 0.5 to 0.6, while mangrove bark, a pronounced catechol tan, reached 0.68. These differences are not so large as was *a priori* to be expected, a fact which greatly facilitates the use of the method for liquor testing, but which proves that the permanganate required is dependent rather on the differences of constitution of the individual tannins than on the catechol or pyrogallol nucleus. It is also evidence that even in those tannins most allied to gallotannic acid, the substance estimated by hide-powder is not simply gallotannic acid, but either includes other less oxidisable matters or compound tannins of a more complex character, and very possibly in many cases, glucosides.

The gallic acid values of the different tannins are characteristics which may be used, like the saponification values and iodine values of fats, as a means of identification. Thus an "oakwood" extract with a gallic acid value over 0.6 may be justly suspected of being a chestnut. Even in genuine extracts the differences in value which are found, no doubt point to real differences in the character of the tannin due to manufacture, mode of growth, or age, which deserve closer investigation.

In this connection it may be interesting to quote some results of detannisation by gelatine (described in Procter's "Leather Industries Laboratory Book" *), as compared with various hide-powders. It has been shown that by this modification of the method, the separation of gallotannic acid from gallic acid is very approximately accurate, although perhaps by a compensation of errors, traces of gallic acid being precipitated and traces of the tannogelatin dissolved in the acid liquor. Addition of more salt diminishes the latter error, but increases the former.

* To 50 c.c. of liquor add 25 c.c. of fresh 2 per cent. gelatine solution, 25 c.c. of a saturated solution of salt containing 50 c.c. of sulphuric acid per litre, and a teaspoonful of kaolin, shake for 15 minutes and filter and titrate 10 c.c. instead of 5 c.c.

TABLE III.
Gallic acid equivalent to non-tannins.

Extract.	Gelatine salt and acid.	Freiberg unchromed powder.	Vienna unchromed powder.	Paessler's chromed powder.	American chromed I.A.L.T.C.
Oakwood, (reputed)	0.255	0.221	0.163	0.149	0.149
Oakwood, Gondolo	0.160	0.144	0.132	0.115	0.115
Chestnut, solid	0.331	0.354	0.320	0.242	0.245
Chestnut, liquid	0.297	0.300	0.297	0.209	0.199

It will be observed that in most cases the non-tannins are highest in the case of gelatine precipitation, though in some cases they are approached or even exceeded by the unchromed hide-powders used by shaking, while those of the chromed powders are invariably much lower. It appears therefore that as regards the oxidisable matters estimated by permanganate, the unchromed powders give results nearer the scientific truth, but the much closer concordance of the chromed powders fully justifies their use for commercial purposes, and further it must be remembered that in gravimetric analysis these oxidisable and generally astringent non-tannins form only a small portion of the whole. The close agreement of Prof. Paessler's lightly chromed powder with that officially chromed, establishes the suitability of the former as a detannising agent for the Löwenthal process, and encourages the hope that a dry chromed powder may ultimately be produced, which will avoid not only the chroming, but the much more troublesome washing immediately before use which is now required.

If the gelatine method is preferred to hide-powder for liquor control it is quite as rapid, and probably less affected by large amounts of non-tannins, but the results are not directly comparable with gravimetric analysis, and some samples of gelatine exercise a slight reducing effect on permanganate, not amounting in blank experiments to more than about 0.2 c.c. per 10 c.c. of the non-tannin filtrate, and probably due to traces of sulphites. This, if desired, is easily determined and allowed for.

DISCUSSION.

Prof. W. M. GARDNER suggested the investigation of the effect of reducing instead of oxidising substances on tannins. The action of the latter was the basis of the methods of estimation at present used. If a definite substance such as benzoic acid could be obtained as a result of reduction, much more definite results might be obtained. Under certain conditions tannic acid and any other phenolic bodies gave benzoic acid on reduction.

Mr. F. W. BRANSON asked if absolutely pure chemicals were necessary when a correction factor could be used.

Mr. H. G. BENNETT said that difficulties were always experienced with certain tannins where the methods of estimation broke down. He emphasised the value of a volumetric method such as the Löwenthal method, which combined speed and accuracy, since the hide-powder process involved difficulties such as the possible presence of difficultly volatile substances like lactic acid, the impossibility of drying the exhausted extract to a constant weight, &c.

Note by Prof. H. R. PROCTER: I have not tested the recently-suggested reduction methods for the investigation of tannins, which are of great scientific interest, but do not seem as yet likely to supersede those in use for practical estimation. In reply to Mr. Branson's question, there is no doubt that in many cases absolutely pure chemicals are of the greatest importance. In the Löwenthal process the purity of the gallic acid is of the highest importance, and the indigo must be free from indigo red and other products which obscure the end-point.

NOTE ON THE DIFFUSION OF CHROMIUM, IRON AND ALUMINIUM SALTS THROUGH GELATINE JELLY.

BY PROF. H. R. PROCTER AND DOUGLAS J. LAW.

The experiments described in the following note were prepared in the first instance as a lecture demonstration, but though the results throughout must merely be regarded as qualitative they appear to present some points of interest which make them worthy of a permanent record.

If a solution of a coloured crystalline salt, such as copper sulphate, is poured on the top of solidified gelatine jelly, it diffuses into it somewhat rapidly, its progress being easily traced by the change of colour in the transparent jelly. It has been shown by Fick that in many cases diffusion in jellies is practically as rapid as in still water. In the case of coloured substances of a less definitely crystalline character the diffusion is slower, and the ultimate penetration less, while solutions of a distinctly colloidal nature either do not penetrate at all or do so to a comparatively small extent. If a mixture of two coloured substances is employed of different degrees of diffusibility two zones of diffusion are formed, of which the deeper consists only of the more diffusible substance. When operating with colourless salts, bases, or acids, it is frequently easy to determine their progress by the addition of a suitable indicator, thus that of strong bases is shown by the addition of phenolphthalein, or that of acids, by the same reagent coloured with a trace of caustic alkali.

As salts of chromium and other metals of the same group are very prone to hydrolysis and the formation of basic salts, it was of interest to determine not merely the progress of the chrome salt but that of the hydrolysed acid, and for this purpose a 5 per cent. jelly was used coloured pink with slightly alkaline phenolphthalein. This was allowed to set in Nessler cylinders, or for the purpose of lantern demonstration, in parallel-sided cells, and the solution to be tested was poured upon the top of the jelly. That gravitation had little influence on the rapidity of the diffusion was proved by repeating a similar experiment with an inverted tube. As the chrome salts diffused into the jelly, their progress was clearly noted by their colour, which, whatever the colour of the solution, is generally in the jelly of a dull bluish green, somewhat

between the colour of the well-known green and violet modifications. As, however, the chrome salts hydrolyse considerably, the penetration of the acid was much more rapid, with the consequence that a broad zone was formed beyond the chrome in which the colour of the phenolphthalein was discharged. As a rule the boundaries of these zones, though naturally shading into each other, were sufficiently sharp to allow of easy approximate measurement, especially as regards the edge of the diffused chrome salts. That of acid was distinctly sharper in the case of chrome alum than in that of chromium chloride solution. The results of these experiments are shown in the following tables, the depth of diffusion being stated in centimetres. Experiments were made with a half-saturated solution of chrome alum containing about 1 per cent. of chromium and with a 10 per cent. solution of chromium chloride containing 1.4 per cent., 10 c.c. being in each case placed above the gelatine in the Nessler tube. As the first experiments were not intended to be qualitative, this solution was not renewed, but it must be observed that under these conditions the diffusing solution must become continuously weakened with the progress of the diffusion, so that in the later stages the diffusion would go on very slowly. Before any calculations therefore could be made, this would have to be taken into account, together with the possible swelling or contraction of the jelly, and if it were possible to apply the method quantitatively it would probably be better to employ larger quantities of the solution kept gently stirred and replaced by new solution before sensible change had taken place in the concentration. Both solutions of the normal salts and others rendered basic with definite additions of sodium carbonate were employed, and one of the most striking facts observed was that the rate of diffusion and the apparent amount of hydrolysed acid was in the case of chrome chloride unaffected by these conditions, and the differences scarcely if at all exceeded that of probable experimental errors, while with the chrome alum, the diffusion of the chromium was rendered much slower, but without any corresponding influence on that of the acid. From a solution of chrome alum rendered green by boiling, the diffusion of acid was much more marked than from the violet normal salt, supporting the view that the change of colour was due to hydrolysis and the formation of a basic salt. As has been noted, the solution of chromium chloride employed was materially stronger than that of the chrome alum, and perhaps this may explain the differences of effect. A further experiment is in progress with solutions of equal chromium concentration.

The rate of diffusion was found to be quite independent of the bore of the tube.

An interesting effect noticed in some of the experiments both with chromium chloride and chrome alum was the production of striae or layers of green parallel to the surface and of greater intensity than the layers above and below. These recall the somewhat similar effects observed in the diffusion of bichromate in gelatine containing traces of silver nitrate, or conversely of silver nitrate in bichromated gelatine. The latter has been recently investigated by R. E. Liesegang (*Kolloide Z.*, 1907, 2, 70), who finds that it is much influenced by the presence of gelatines or decomposed gelatine. Ostwald has explained the phenomenon as due to the existence of a supersaturated solution of silver chromate which diffuses without precipitation to a certain concentration at which "germs" are spontaneously formed, and the concentration falls to saturation, and again diffuses till it again becomes sufficiently supersaturated. Liesegang points out that the gelatines increase the solubility of silver chromate. Although no two salts which mutually give rise to a less soluble one are present in the green chrome solutions, the explanation is probably somewhat similar. The hydrolytic dissociation and diffusion of the acid makes the salt continually more basic until at last a part becomes incapable of further diffusion, and possibly acts as a semipermeable membrane to the more basic part, while the more acid or normal portion diffuses further until it in turn becomes too basic. It is also possible that the basic salt passes spontaneously from the sol to the gel condition at a certain degree of basicity, leaving a more acid salt in solution, as it is well known that when separation takes place in such basic solutions, the portion unprecipitated is much more acid than before, the gel formation being only reversible in presence of considerable excess of acid.

The phenomena in the case of iron and aluminium salts are very similar in character to those just described, the diffusion of the acid always considerably preceding that of the base. In the case of ferric chloride, the salt fixed is of the deep brown characteristic of basic ferric salts. With alumina it is of course colourless, but may be made visible by the addition of a trace of yellow logwood infusion with which alumina forms a violet lake.

The experiments described are not only interesting as demonstrating in a striking way the hydrolysis of such salts, but also illustrate what has long been taught by one of us, and has recently been fully proved by Stiasny (*Collegium*, 1908, 337; this *J.*, 1908, 1030), that the acid and the colloidal base are absorbed independently by the amphoteric gelatine or gelatinous hide-libre, and that either may be absorbed in excess according to the conditions of the experiment.

Journal and Patent Literature.

PATENT SPECIFICATIONS may be obtained by post by remitting as follows:—

English.—8*l.* each, to the Comptroller of the Patent Office, C. N. Dalton, Esq., Southampton Buildings, Chancery Lane, London, W. C.

United States.—1*s.* each, to the Secretary of the Society.

French.—1 fr. 25 c. each, to Belin et Cie., 56, Rue des Francs Bourgeois, Paris (3e.).

German.—1 mark each (with full particulars) to Kaiserlich Patentamt, Berlin, Germany.

I.—PLANT, APPARATUS, AND MACHINERY.

PATENTS.

Removal of liquid from solid materials; Apparatus for the —. P. J. Ogle, London. From F. St. Q. Cockburn, Traag, Norway. Eng. Pat. 2815, Feb. 7, 1908.

The material to be filtered is fed continuously from a hopper which rotates over a horizontal, annular filter. The latter is supported over a vacuum chamber and the liquid is sucked through, leaving the solids on the surface of the filter. Immediately in front of, and attached to, the rotating hopper is a curved skimming blade which strips off the cake of solids from the filter. The place of the removed solids is at once taken by fresh material from the hopper, so that the vacuum is not "broken" and the process is continuous. The space below the filter is divided by radial partitions into sections, each connected to a double vacuum receiver. Washing liquid is sprayed on to the surface of the deposit by a rotating arm which follows the feed-hopper at a determined distance. The filtrate and wash-water passing through the filter are directed into one or other of the double vacuum receivers by a butterfly valve operated by the rotating frame which carries the skimmer, feed-hopper, and wash-water pipe.—W. H. C.

Pressure-filters; Plate for —. C. W. Merrill, Lead, S.D. U.S. Pat. 912,867, Feb. 16, 1909.

The claim is for a filter-plate having a solid central web, the surface of which is corrugated. The corrugations are arranged in such a manner that they form concentric polygons. The sides of the polygons are intersected by drainage grooves, each of which is shorter than the shortest anterior surface dimension of the filter-plate.—W. H. C.

Filtration and purification of gases and vapours. G. F. Jaubert. Fr. Pat. 394,472, Dec. 5, 1907.

The purifying material is contained in closed, cylindrical, metal casings or cartridges, the ends of which are made of thin material so that they may be easily perforated. The case or cartridge is placed between two adjustable tubular supports, each of which is provided with projecting

teeth so that when they are forced together to grip the cartridge, the teeth perforate the thin ends and allow the gas, which enters by one support and leaves by the other, to pass through the purifying material. The object of the arrangement is to prevent the deterioration of the purifying material when stored before use and to allow the introduction of the cartridge into the stream of gas without admitting any air.—W. H. C.

Packing for filter-press elements. L. Schargel. Ger. Pat. 206,711, March 13, 1908.

The packing consists of a flat ring, *g*, of ebonite or other suitable material, shown in cross-section, in Figs. 1 and 2, on which are fastened rings, *a*, *b*, of rubber, of any suitable cross-section. The rubber ring, *a*, does not cover the whole width of *g*, but leaves a portion, *c*, free. In this portion cuts, *f*, are made at intervals as shown in Fig. 3, corresponding to pieces, *d*, on the filter-press elements, so that the packing can easily be put in place.—A. S.

Liquids which readily deteriorate [e.g., sugar juices]; Apparatus for the filtration of —. H. Hoppe. Ger. Pat. 206,408, April 13, 1906.

A NUMBER of small sand-filter boxes are connected to common inlet and outlet pipes, the connections between the boxes and the inlet pipe being of such a kind that they

can be easily opened and closed. A lifting and transporting device is provided for removing the filter-boxes to the sand-washing apparatus. In the apparatus shown, the filter-boxes have conical bottoms with central pipes which project downwards into openings, provided with rubber rings, in the inlet-pipe for the liquid to be filtered or into the discharge pipe for the wash-water. The liquid to be filtered, e.g., sugar juice, passes upwards through the filters. Above the filter-boxes is a pipe for supplying wash-water.—A. S.

Evaporating apparatus [for sugar solutions, etc.]. Maschinenfabrik Grevenbroich, Grevenbroich, Germany. Eng. Pat. 20,972, Oct. 5, 1908. Under Int. Conv., Oct. 8, 1907.

The side of the tubular heating chamber, 1, is carried upwards beyond the bottom of the vapour chamber, 4, and the ends of the tubes, 2, also project beyond the upper tube-plate. The circulating pipe, 6, which is closed above and below, projects beyond the upper and lower tube-plates and is perforated both above and below, as shown at *h*. The liquid to be evaporated (e.g., sugar solution) enters through 10, passes up the tubes, 2, and overflows. A portion returns through the perforations, *h*, to the circulating pipe, 6, and another portion passes through the perforations, *i*, into the annular space, 5, from whence it overflows through *b*. Any froth formed overflows into the annular trough, 7, carrying with it any separated impurities. From 7, these are removed with the liquid by the pipes, *g*, *c*, and any separated liquid returns through *d* to the annular chamber, 5.—W. H. C.

Drying air; Method of and apparatus for —. H. C. Gardner, Chicago, Ill. U.S. Pat. 910,525, Jan. 26, 1909.

Air is dried by cooling it and exposing it to the action of a hygroscopic agent. The apparatus comprises three chambers. A coiled pipe conveying a refrigerating liquid passes through the first and third of the chambers, and the second chamber is traversed by tubes and forms a heat exchanger for the air, so that the cold dry air leaving the apparatus assists in the cooling of the moist air on its way to the drying chamber. The air is cooled in the first chamber, and then passes through the tubes in the heat exchanger and thence through the third chamber. A hygroscopic solution is distributed over the coiled pipe in this latter chamber, and the solution is kept in circulation and maintained at approximately the same strength throughout the process. The dried air then passes around the tubes in the heat-exchanger to the outlet of the apparatus.—A. T. L.

Kiln. J. E. Kennedy, New York. U.S. Pat. 911,658, Feb. 9, 1909.

A WATER-JACKETED tube is disposed axially within a horizontal rotary kiln, and air and gas mixed with products of combustion from the chimney are introduced into the interior of the tube by pipes. The gas and air escape into the kiln through symmetrically disposed openings in the jacketed tube, so that each part of the kiln receives substantially equal supplies of air and gas.—W. H. C.

Percolator and extractor. C. Warburton, Pawtucket, R.I. U.S. Pat. 912,634, Feb. 16, 1909.

A PERCOLATING receptacle is interposed between a closed liquid reservoir above and a closed liquid receiver below. The receiver is connected to the liquid reservoir by an air-pipe in the length of which the bulb of a rubber hand-pump is interposed. On compressing the bulb, air is withdrawn from the receiver and a partial vacuum is created therein. The air so withdrawn is forced into the upper liquid reservoir and produces a pressure on the surface of the percolating liquid.—W. H. C.

Air pyrometers. M. Arndt, Aachen, Germany. Eng. Pat. 2914, Feb. 10, 1908.

SEE FR. Pat. 388,992 of 1908; this J., 1908, 970.—T. F. B.

II.—FUEL, GAS, AND LIGHT.

Irish peat industries; Reports upon the —. Part II. H. Ryan. Economic Proc. Roy. Dublin Soc., 1908, 1, 465–546. (See this J., 1907, 1130.)

THE subject is treated under the following headings:—*Section I. Peat fuel industries.* 1. Properties of fuel; general remarks on peat fuel. 2. Cutting of turf in Ireland; peat digging machines. 3. Drying or "sawing" turf; defects of turf. 4. Hand-turf. 5. Press-turf; wet press processes, centrifugal press, and dry press processes. 6. Machine-turf. 7. Drying machine turf. 8. Electro-peat. 9. General plan for a turf factory; use of peat fuel. *Section II. Peat distillation industries.* 1. Turf-charcoal. 2. Coking in heaps. 3. Coking in furnaces. 4. Coking in retorts; electrical coking process; coking by superheated steam. 5. Properties of turf-charcoal; turfite or half-coked turf; utilisation of by-products; turf-tar; extraction of acetic acid and ammonia from the "gas-water"; light petroleum, lubricating oil, and wax. 6. Properties and average amounts of the by-products. 7. Turf-gas; illuminating gas from turf. 8. Heating gas from turf; turf generator gas. 9. Distillation of turf

at low temperatures; preparation of ammonium sulphate from turf. Three plates, tables showing the Irish imports and exports (1904, 1905, and 1906) of peat-moss litter and peat fuel, and a bibliography, are appended to the paper.—A. S.

Coal production and consumption in the principal countries of the world. Board of Trade J., March 4, 1909. [T.R.]

THE production of coal in the five principal coal-producing countries of the world in 1905, 1906, and 1907 was as follows:—

Countries.	1905.	1906.	1907.
	tons.*	tons.*	tons.*
United Kingdom . . .	236,129,000	251,068,000	267,831,000
Germany	119,350,000	134,914,000	140,885,000
France	34,652,000	32,920,000	35,586,000†
Belgium	21,506,000	23,191,000	23,324,000
United States of America	350,821,000	369,783,000	428,896,000‡

* Tons of 2240 lb. † Provisional figures. ‡ Including lignite.

The total known coal production of the world (exclusive of brown coal or lignite) in 1907 was about 1,000 million tons, of which the United Kingdom produced rather more than one-fourth.

The following statement shows the production of coal in the principal British Colonies and Possessions in the years 1905, 1906, and 1907. The amounts are in every case stated in tons of 2240 lb.:—

Country.	1905.	1906.	1907.
	tons.	tons.	tons.
British India	8,418,000	9,783,000	11,147,000*
Australia	7,494,000	8,596,000	9,681,000*
New Zealand	1,586,000	1,730,000	1,831,000*
Canada	7,739,000	8,717,000	9,385,000*
Transvaal	2,327,000	2,583,000	2,574,000
Cape of Good Hope . . .	147,000	128,000	129,000
Natal	1,129,000	1,239,000	1,530,000
Orange River Colony . . .	106,000	235,000	446,000

* Provisional figures.

The consumption of coal in some of the chief consuming countries is shown in the following statement, in which the countries are given in the order of importance as coal consumers in 1907:—

—	1905.	1906.	1907.
	tons.	tons.	tons.
United States	343,281,000	361,602,000	417,875,000
United Kingdom	169,017,000	174,361,000	182,674,000
Germany	106,716,000	119,282,000	128,411,000
France	45,915,000	49,441,000	52,885,000
Russia	23,604,000*	25,489,000*	24,708,000*
Austria-Hungary	19,314,000	21,234,000	24,257,000
Belgium	19,661,000	22,468,000	22,805,000

* Provisional figures.

Lignite.—The statistics of lignite production show that the principal producing countries are Germany, Austria, and Hungary, which in 1906 produced 55,513,000 tons, 23,779,000 tons, and 6,263,000 tons, respectively, whilst the provisional figures available for the production of Germany in 1907 show a production of 1,542,000 tons. In Austria the output of lignite for 1907 was 25,840,000 tons. The quantity of lignite produced in the United States is included in the figures of coal produced, which have already been given; the best available figures giving the production of lignite separately relate to 1905, when it amounted to 6,149,000 tons. In no other country does the quantity produced reach one million tons. In the United Kingdom it has in some years been nil.

Ethylene; Synthesis of — from carbon monoxide and hydrogen. E. Orlov, J. Russ. Phys.-Chem. Ges., 1908, 40, 1588—1590. Chem. Zentr., 1909, 1, 735.

A MIXTURE of hydrogen and carbon monoxide was led through a glass U-tube filled with a catalytic substance and heated at 95—100° C. The catalytic substance was prepared by impregnating pieces of coke with a solution of nickel nitrate and palladium-ammonium chloride, and subsequently heating. The gases leaving the U-tube contained up to 6.6 per cent. of ethylene. Under similar conditions no reduction of carbon dioxide to formaldehyde could be detected, but at higher temperatures carbon dioxide yielded some ethylene and methane. —A. S.

Gases; The ignition-temperatures of —. H. B. Dixon and H. F. Coward. Chem. Soc. Proc., 1909, 26, 67.

THE temperature to which two gases must be heated in order that, when brought into contact, they will inflame immediately has been determined by passing an inflammable gas up a tube, terminating in a nozzle, fixed in the centre of a second tube conveying a current of air or oxygen, and electrically heated. Thus no reaction occurred during the preliminary heating of the gases. The temperature of the gas 2 mm. below the nozzle was measured by means of a protected thermo-junction. The ignition-temperature of hydrogen thus obtained was constant, within 10°, under variation of the following circumstances: (1) The rates of flow of the gases, within wide limits. (2) The size, material, and surface condition of the jet and of the walls of the furnace. (3) The rate of heating of the furnace. (4) The position of the thermo-junction, either inside or just outside the nozzle. The ignition-temperature was at first decreased some 20° by increasing the diameter of the outer tube, but a limit was then reached when doubling the diameter produced no further decrease. The ignition-temperature was raised 5° by working under half an atmosphere pressure, but decreased by 30° under a pressure of two atmospheres. The ignition-temperature of hydrogen in air is the same as in oxygen. The results obtained at atmospheric pressure are given in the following table. The paraffins and ammonia gave numbers varying with the rates of flow of the gases, as well as with the size of the furnace tube, so that their ignition-temperatures are not so clearly defined as those of hydrogen, carbon monoxide, and the other gases. It was also stated that alteration of the proportion of the gases within wide limits had no effect on the ignition-temperature.

Gas.	Ignition temperature.			
	In oxygen.		In air.	
	Between.	Mean.	Between.	Mean.
Hydrogen	589—590	585°	580—590°	585°

PATENTS.

Fuel for internal combustion engines, and manufacture of same. S. Barth. Fr. Pat. 394,386, Sept. 17, 1908. Under Int. Conv., Aug. 6, 1908.

A CELLULAR substance such as wood, straw, peat, coal, cellulose, celluloid, paper, etc., is ground to a very fine powder and sifted to remove fibres. Any resinous or agglutinant constituents are removed, and nitrates or other substances readily yielding oxygen are added to increase the force of the explosions, if desired. The fuel is used in place of the usual liquid fuels for internal combustion engines.—A. T. L.

Briquettes; Process of mixing binding materials with small coal for the manufacture of—Gewerkschaft des Steinkohlenbergwerks Adler. Fr. Pat. 394,740, Sept. 28, 1908.

IN the manufacture of briquettes, the binding materials, in a very finely divided state, are blown into the mass of small coal by means of steam or compressed air. The binding material (e.g. pitch or naphthalene) is used in the form of very fine powder or a liquid spray, and the compressed air may advantageously be preheated.

—W. C. H.

Smoke; Purifying and rendering innocuous—H. Beernaert. Fr. Pat. 394,634, Dec. 2, 1907.

THE coal charged into the furnaces is previously mixed with a small proportion of lime or calcium carbonate in order to prevent the disengagement of sulphur dioxide. The quantity so added is adjusted according to the percentage of sulphur contained in the coal.—W. H. C.

Coke ovens; Horizontal-flued—A. Lupton, London, and T. H. Riley, Sheffield. Eng. Pat. 8926, April 24, 1908.

To facilitate the repair of coke-ovens having horizontal heating flues, superposed flues are separated by "header bricks" which rest at one end upon the oven wall, and at the other end upon the central wall separating adjacent flues. The outer ends of the "header bricks" are protected by grooved and tongued facing bricks, and the space between their inner ends is occupied by vertical slabs. The thickness of the slabs may be varied to give the usual tapering form to the oven. When any of the bricks in the oven walls require renewing, the walls of the heating flues above the repair are supported during the operation by props beneath the sound "brick headers."—A. T. L.

Gas; Process of manufacturing—from coal. B. Thümmel, Dresden-Naustütz, Germany. U.S. Pat. 912,509, Feb. 16, 1909.

GAS for actuating an internal-combustion engine is generated by causing powdered coal to fall intermittently upon a surface heated by the exploded gases of the engine, pressing the coal against the heated surface, and removing the non-volatile residue of the coal before the next charge of coal is supplied.—A. T. L.

Gas-producer. E. Lawrenz, Lynn, Mass. U.S. Pat. 912,580, Feb. 16, 1909.

THE producer comprises a cylindrical casing and a hollow lining formed of two tiers of segmental iron blocks. Water is circulated through the hollow blocks forming the upper tier, and the hot water from the upper tier is led into the lower tier of blocks. The steam generated in the lower tier of blocks is led into the producer with air which has circulated through a passage between the casing and the hollow lining.—A. T. L.

Gases; Apparatus and process for manufacturing and mixing—and delivering the mixed gases to gas-engines. B. Loomis, Hartford, Conn., and H. Pettibone, New Rochelle, N.Y., Assignors to Power and Mining Machinery Co., New York. U.S. Pat. 912,698 and 912,699, Feb. 16, 1909.

PRODUCER gas and water gas are generated alternately in a producer, and after passing through scrubbing and cleansing apparatus, the gases are collected in separate holders. The water gas and producer gas are then mixed in a third gas-holder and the mixture is delivered to an engine.

—A. T. L.

[Producer] gas; Process and apparatus for the generation of—with the admission of air and steam at the centre of the producer. R. Panck. Fr. Pat. 394,810, Sept. 30, 1908.

To prevent the formation of clinker on the grate, the whole or the greater part of the steam is admitted through openings near the apex of a central conical grate or tuyère. The interior of the grate is divided by a horizontal partition

into an upper and a lower compartment. The whole, or the greater part of the air is introduced through the lower compartment, and the whole or the greater part of the steam through the upper compartment. In one form, the conical grate is mounted eccentrically on a rotating table forming a water-trough in the base of the producer, and the grate is provided with external helical steps to facilitate the discharge of clinker. The upper and lower parts of the grate may be both conical, or the lower part may be cylindrical. The two parts may be separate, and the grate may be cooled by the circulation of water through a pipe coiled around it.—A. T. L.

[Suction] gas-producer. V. G. Montaland-Davray. Fr. Pat. 395,103, Oct. 9, 1908. Under Int. Conv., Oct. 10, 1907.

THE producer, which works with a down-draught and is suitable for semi-bituminous coals, comprises a cylindrical brick-lined casing surmounted by an annular vaporiser and an annular fuel-container. The fuel in the container is free to fall as the fire descends. Air enters through the open vertical passage formed by the annular fuel-container, and the fire can be poked at any time through this passage. Steam from the vaporiser passes through a cock controlled by the engine governor and enters the air-inlet passage just above the top of the fire. The fuel column rests upon a horizontal grate having rectangular openings. Vertical pokers, worked by a lever from outside, may be passed through these openings, and horizontal pokers, also worked from outside, may be passed between the vertical pokers when the latter are raised, in order to discharge the clinkers over the edge of the grate. The hot gases leave the producer through an opening above the level of the grate, and pass through a coke-scrubber and a filter of wood-fibre, and finally to the engine.—A. T. L.

Electric incandescent lamp filaments. The British Thomson-Houston Co., Ltd., London. From General Electric Co., Schenectady, N.Y., U.S.A. Eng. Pat. 10,590, May 15, 1908.

TUNGSTEN or other suitable refractory metal powder is made into a paste with gelatinous zirconium oxalate and extruded into threads. The latter are dried and heated, whereby the oxalate is decomposed into oxide and the filament is sintered together.—W. H. C.

[Carbon] filaments for incandescence electric lamps; Manufacture of—K. Rittersberg and H. Rubert. Fr. Pat. 394,302, Sept. 15, 1908.

THE carbon is obtained by carbonising a vegetable oil. This carbon is mixed into a paste with resin and a binding agent, and the mixture formed into filaments. The filaments are rendered conductive and are finished by heating in a furnace to 800°—1000° C. The filaments have a very high specific resistance, a life of 1000 hours, and an efficiency of about 1 watt per candle-power.—A. T. L.

Metallic filaments for incandescence lamps. Wolfram Lampen Act.-Ges. Fr. Pat. 394,585, Sept. 23, 1908. Under Int. Conv., Oct. 7, 1907.

THE patent relates to a process for removing carbon from filaments of tungsten, molybdenum, osmium, chromium, tantalum, etc., or of alloys of these metals. Instead of oxidising the carbon, the filaments are heated to redness by the passage of an electric current in an atmosphere of pure dry hydrogen and sulphuretted hydrogen. The carbon is converted into carbon bisulphide, and the metallic sulphides formed are reduced by the hydrogen.—A. T. L.

Incandescence electric lamps; Process for preventing the volatilisation of metallic filaments in—Bergmann-Elektrizitäts-Werke Akt.-Ges. Fr. Pat. 394,823, Oct. 1, 1908. Under Int. Conv., Oct. 3, 1907.

THE process consists in the introduction of traces of a complex gas, and more particularly traces of phosphoretted hydrogen, into the lamp bulb. The explanation suggested is that in consequence of the low velocity of the molecules compared with that of the hydrogen molecule, the electric discharges which are probably the cause of volatilisation in a lamp containing hydrogen, are prevented.—A. T. L.

Retort for the distillation of coal and other carbonaceous substances. T. Parker, London. U.S. Pat. 913,552, Feb. 23, 1909.

SEE Fr. Pat. 380,017 of 1907; this J., 1907, 1271.—T. F. B.

Gas-producer. G. Hatton, Brierley Hill. U.S. Pat. 912,373, Feb. 16, 1909.

SEE Eng. Pat. 13,877 of 1904; this J., 1905, 666.—T. F. B.

Metallic conductors [incandescence filaments] of high resistance; Refractory —. Cie. Franç. pour l'Exploitation des Proc. Thomson-Houston. Fr. Pat. 395,163, Oct. 12, 1908.

SEE Eng. Pat. 24,707 of 1907; this J., 1908, 849.—T. F. B.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, PETROLEUM, AND MINERAL WAXES.

Destructive distillation of pit-coals. E. J. Constan and E. A. Kolbe. J. Gasbeleucht., 1908, 51, 669—673, 693—699.

THE authors studied the destructive distillation of 11 coals from France, a Spanish coal from the Pyrenees, and a French lignite. The results agree with the rule given by Sainte-Claire-Deville and Bunte for gas-coals, that the greater the proportion of oxygen in the coal, the smaller is the yield of coke and the greater the yield of volatile substances, and the greater also the quantity of moisture in the air-dried coal. The results also agree with the observation of Constan and Schläpfer that, in general, the composition and the calorific value of the coke are independent of the chemical composition of the coal, and are determined chiefly by the temperature and duration of the distillation process. The varying rates at which gas was made during the progress of the distillation were observed; the higher the percentage of volatile matter in the coal, the greater was the yield of gas during the first 10 minutes, and almost the whole of the gas was liberated during the first 25 minutes in all cases. The greater the yield of gas, the higher were the percentages of carbon dioxide, heavy hydrocarbons, carbon monoxide, and methane, and the lower the percentage of hydrogen, and in general, the lower also was the calorific value of the gas per unit weight. The heat balance of the distillation showed an average loss of 4.4 per cent. of the heat of combustion of the coal. The authors consider that no formula, such as that given by Goutal, will enable the calorific value of coal to be accurately calculated from the proximate analysis, as the proportion of fixed carbon in the ash-free coal increases, the calorific value increases to a maximum with coals containing 18—22 per cent. of volatile matter, and then decreases with semi-anthracitic and anthracitic coals. The paper also contains full details of the composition of the coke, and of the yield, composition, and calorific value of the gas, tar, and pitch.—A. T. L.

Indene; A sodium derivative of —. R. Weissgerber. Ber., 1909, 42, 560—572.

WHEN pure or crude indene is mixed with sodamide, heat developed, ammonia is evolved, and the sodium compound of indene,

formed. The mixture is warmed for 2 hours to 110—50° C., to complete the reaction. When crude indene has been used, the unattacked hydrocarbons are separated from the reaction product by distillation in a vacuum. Still purer product is obtained by adding the calculated quantity of metallic sodium to crude indene, warming the mixture for 5—6 hours to 120°—130° C., and passing in a slow stream of ammonia. At 140°—150° C. the reaction

between sodium and indene proceeds without the use of ammonia; if about 2 per cent. of an organic base such as aniline, toluidine, or pyridine be added, the temperature need only be maintained at 100—105° C. for 3 hours. The reaction affords a very convenient method of obtaining pure indene from coal tar (see Ger. Pat. 205,465, this J., 1909, 84).—J. C. C.

Indene in coal tar. A. Spilker and A. Dombrowsky. Ber., 1909, 42, 572—573.

PURE indene prepared from the sodium compound (see preceding abstract) melts at —2° C., boils at 182.2—182.4° C. (corr. 761 mm.); sp. gr. at 15° C./15° C., 1.0002; and $n_D^{20}=1.5773$ at 18.5° C. The dibromide is quite stable and crystallises from petroleum in colourless, stout prisms m. pt. 31.5—32.5° C. It gives a characteristic magenta red coloration with cold, concentrated sulphuric acid, which disappears on dilution with water.—J. C. C.

o-Nitro-p-cresol; Behaviour of — towards sulphuric acid. G. Schultz and O. Löw. Ber., 1909, 42, 577—578.

By treating *o*-nitro-*p*-cresol with fuming sulphuric acid, acetylaerylic acid is formed in accordance with the equation,

—J. C. C.

Polynaphthenic acids. K. Charitschkow. J. Russ. Phys.-Chem. Ges., 1908, 40, 1757—1774. Chem. Zentr., 1909, 1, 851.

By the oxidation of Caucasian petroleum with atmospheric oxygen in presence of caustic soda, the author obtained non-crystallisable polynaphthenic acids, of sp. gr. 1.2, easily soluble in alcohol, benzene, chloroform, ether, and carbon bisulphide, slightly soluble in petroleum spirit. These acids decompose when heated *in vacuo*; they are dark-coloured, owing to the presence of asphaltum, into which they are gradually converted on keeping. They give Legal's ketone reaction (red coloration with sodium nitroprusside). The blue copper salts of the acids, unlike those of naphthenic acids, are only slightly soluble in water and hydrocarbons. The esters of the acids are oily, odourless compounds which can be readily separated from the more volatile esters of naphthenic acids. A polynaphthenic acid prepared from a petroleum fraction boiling at 169—171° C., corresponding to a decanaphthene, had the composition, $\text{C}_{20}\text{H}_{22}\text{O}_4$. On reduction with hydriodic acid in a sealed tube, it yielded a hydrocarbon resembling the heavy oil obtained on the distillation of petroleum. The polynaphthenic acids yield nitro-derivatives similar to those obtained by the action of nitric acid on the higher-boiling petroleum distillates. An acid resembling the polynaphthenic acids was obtained by oxidation of a hydrocarbon prepared from menthol by converting the latter into the corresponding iodide, and heating with phosphorus and iodine. The polynaphthenic acids probably contain two hydroxyl groups in addition to the carboxyl group.—A. S.

Emulsification. Marshall. See XXIV.

PATENTS.

Extinguishing fires from burning benzine, petroleum, oil of turpentine, and the like. W. E. Evans, London. From W. Graaff und Co., Ges.m.b.H., Berlin. Eng. Pat. 17,156, Aug. 14, 1908.

THE patentee proposes that fires be extinguished by applying to them a solution of bromine or iodine in carbon bisulphide, chloroform, carbon tetrachloride, etc. The vapours of bromine or iodine set free by the heat, being of high specific gravity, settle down as a layer on the burning oil, and by preventing the access of air, extinguish the fire.—W. H. C.

Distillation of bituminous coal or similar carbonaceous substances. T. Parker. Fr. Pat. 395,998, Oct. 9, 1908.

SEE Eng. Pat. 18,418 of 1907; this J., 1908, 1146.—T. F. E.

IV.—COLOURING MATTERS AND DYESTUFFS.

Dyestuffs: Relation between sensitiveness to light and constitution of —. K. Gebhard. Z. angew. Chem., 1909, 22, 433—435.

THE author finds that the sensitiveness of dyestuffs in aqueous solution towards light is favoured by a quinonoid structure, but the presence of certain groups in the molecule has also a great effect. In general, increase in the number of hydroxyl groups increases the sensitiveness to light, as is shown in the case of dyestuffs of the Alizarin class except when a third hydroxyl group enters the second benzene ring, as in Alizarin Blue X and Alizarin SX, when the sensitiveness is reduced. The sodium salts of weak acids are also favourable to attack by light, thus Acid Magenta is more sensitive than Diamond Magenta. Further, the replacement of one of the hydrogen atoms in an amino-group renders a dyestuff more sensitive to light; thus Rhodamine G is more sensitive than Rhodamine B. Hydrogen ions have a detergent effect on the light-sensitiveness, Gallein, as free acid, being more stable than when in the form of a salt. Other agents having a stabilising effect are the amino-group and the SO_4^{2-} , Br^- , and Cl^- ions. Dyestuffs containing groups tending to make them sensitive to light are rendered more stable by the introduction of stabilising groups and *vice versa*. —J. C. C.

PATENTS.

Azo dyestuffs; Manufacture of —. R. B. Ransford, London. From L. Cassella und Co., Frankfurt-on-Maine, Germany. Eng. Pat. 2721, Feb. 6, 1908.

By combining one molecule of diazotised *m*-aminophenyl-5-hydroxy-1-2-naphthimidazole-7-sulphonic acid or its dihydro derivative (hereinafter called "imidazole acids"), with a second molecule of imidazole acid, polyazo dyestuffs are obtained containing a double imidazole group. This group may be formed by combining the molecules in an alkaline solution and the product may then be combined with one molecule of a diazo compound, such as *p*-diazobenzenesulphonic acid. An easily soluble dyestuff of excellent affinity is thus produced, whereas the analogous dyestuff containing only one imidazole group hardly stains cotton. Dyestuffs containing the double group may also be obtained by diazotising the monoazo dyestuffs prepared from the imidazole acids and then combining with a second molecule of imidazole acid. If these disazo dyestuffs are diazotised and developed on the fibre, dyeings fast to washing and to acids are obtained. If they are diazotised in substance and combined with a naphtholsulphonic acid, a series of cotton dyestuffs is obtained, the members of which are soluble, fast to acids, and yield yellowish-red to bluish-red shades. Example: 19.9 kilos. of the sodium salt of sulphaniic acid are diazotised with 36 kilos. of hydrochloric acid of 21° B. and 7 kilos. of sodium nitrite. The diazo compound is introduced into a well-cooled solution of 38 kilos. of *m*-aminophenyl-5-hydroxy-1-2-dihydronaphthimidazole-7-sulphonic acid which has been dissolved together with 40 kilos. of anhydrous sodium carbonate. After two hours the mixture is heated to 70° C. and the dyestuff is then salted out and filtered off. For further diazotisation, the dyestuff is stirred to a paste with water and, after cooling, 48 kilos. of hydrochloric acid of 21° B. and 7 kilos. of sodium nitrite are added. The diazo compound is formed after about 6 hours. It is introduced into a solution of 38 kilos. of *m*-aminophenyl-5-hydroxy-1-2-dihydronaphthimidazole-7-sulphonic acid and 40 kilos. of anhydrous sodium carbonate. After heating for a short time, the dyestuff is salted out, filtered off, and dried. It forms a brown

powder which gives a brilliant red aqueous solution. In concentrated sulphuric acid it dissolves with a bluish-red colour. It dyes cotton scarlet shades, which when developed with β -naphthol yield scarlet red shades. —P. F. C.

Azo colouring matter (dyestuff); Manufacture of —. J. Y. Johnson, London. From Badische Anilin und Soda Fabrik, Ludwigshafen on Rhine, Germany. Eng. Pat. 28,272, Dec. 28, 1908.

By combining diazotised 2:6-dinitroaniline with β -naphthol, a scarlet dyestuff is obtained which is especially suitable for use in the form of its lakes, since these are fast to water, alcohol, lime, and light, and are insoluble in oil and do not sublime. Example: 18.3 parts of 2:6-dinitroaniline are diazotised in concentrated sulphuric acid by means of nitrosyl sulphate and the solution is run into an aqueous suspension of 15 parts of β -naphthol to which ice has been added. The combination may also be carried out in the presence of sodium carbonate, lime, acetate, or a substratum, or Turkey red oil or soap may be added. —J. C. C.

6-Nitro-3-chloro-1-aminobenzene-4-sulphonic acid or 6-nitro-3-chloro-1-aminobenzene; Process for preparing —. Badische Anilin und Soda Fabrik. Ger. Pat. 206,345, March 7, 1908.

By the sulphonation of 3-chloro-1-acetaminobenzene, the 4-sulphonic acid is obtained; this is nitrated, and the resulting mass is diluted with four or five times its weight of water and heated to 70°—80° C., when the acetyl group is readily removed; an alkali salt of 6-nitro-3-chloro-1-aminobenzene-4-sulphonic acid can then be precipitated by addition of an alkali chloride; if the quantity of water used be such that there are 20—30 parts to each 100 parts of sulphuric acid present, and the heating is carried to 100 C. for several hours, the sulpho-group as well as the acetyl group is eliminated, and 6-nitro-3-chloro-1-aminobenzene results. —T. F. E.

Azo-dyestuff. A. Bergdolt, Assignor to Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. U.S. Pat. 912,356, Feb. 16, 1909.

By combining diazotised 1:8-aminonaphthol with 1:8-dihydroxynaphthalene-4-sulphonic acid, a dark blue azo-dyestuff is produced. This dyes wool from an acid bath in violet shades which are changed to violet-black after chroming. —J. C. C.

Indigo; Production of halogen derivatives of —. Farbenfabr. vorm. F. Bayer und Co. Fr. Pat. 394,861, Sept. 16, 1908. Under Int. Conv., Oct. 4, 1907, Jan. 24, Feb. 29, and Mar. 7, 1908.

SEE Eng. Pat. 4423 of 1908; this J., 1909, 18. In addition to the details given in the Eng. Pat., the bromination of dichloroindigo with the formation of dichlorodibromoindigo is described; this gives redder shades than tetrabromoindigo. Further it is shown that dibromoindigo can be obtained by adding 30 parts of sodium bromide to a mixture of 10 parts of Indigo and 300 parts of concentrated sulphuric acid. —J. C. C.

Alizarin; Manufacture of —. Farbenfabr. vorm. F. Bayer und Co. Fr. Pat. 395,137, Oct. 10, 1908. Under Int. Conv., Feb. 22, 1908.

ALIZARIN is prepared in good yield and of a high degree of purity by heating anthraquinone with highly concentrated alkali lye (80 per cent.); although by former methods where alkali lyes of up to 50 per cent. strength were used and the presence of an oxidising agent was necessary to ensure a good yield, in the present process the addition of a reducing agent actually increases the yield. Example: A mixture of 1200 kilos. of alkali lye (mixture of caustic soda and potash) of 80 per cent. strength, 100 kilos. of sodium sulphite, and 200 kilos. of anthraquinone is heated to 200° C. until the quantity of alizarin does not increase.

The mass is then poured into water, filtered, and the filtrate acidified. The alizarin may also be precipitated by forming its calcium salt and decomposing this with acid. In a second example 200 kilos. of anthraquinone are heated with 800 kilos. of the same alkali without the addition of sodium sulphite.—J. C. C.

Sulphide dyestuffs and their manufacture; New —. Act.-Ges. f. Anilinfabr. Fr. Pat. 394,832, Oct. 2, 1908.

By heating *o*-, *m*-, or *p*-toluidine or thio-*p*-toluidine or the acetyl or formyl derivatives of the former bases with phenylenediamine or *p*-nitroaniline and sulphur, sulphide dyestuffs are produced which dye cotton direct from a sulphide bath in fast yellowish olive to olive shades. Example: A mixture of 107 parts of *p*-toluidine, 162 parts of *p*-phenylenediamine, and 167 parts of sulphur is heated in a reflux apparatus to 220°–240° C. for 8 hours. The mass is dissolved in a mixture of 2460 parts of crystallised sodium sulphide and 1230 parts of water and the dyestuff is precipitated by means of a current of air or by acidifying. In a second example a mixture of 214 parts of *o*-toluidine, 420 parts of *p*-nitroaniline, and 1780 parts of sulphur is treated in a similar manner.—J. C. C.

Gallocyanines with amines; Process for preparing condensation products of —. Farbwerke vorm. L. Durand, Huguenin, und Co. Ger. Pat. 206,465, Feb. 29, 1908. Addition to Ger. Pat. 192,529, Nov. 20, 1906.

ACCORDING to the main patent, the condensation of gallocyanines with amines was carried out in presence of aromatic nitro-hydrocarbons. According to the present patent, the condensation is effected in presence of a brisk current of oxygen; substances which assist the action of the oxygen, such as manganese, iron, or vanadium compounds, may also be employed to facilitate the process.

V.—PREPARING, BLEACHING, DYEING, PRINTING, AND FINISHING TEXTILES, YARNS, AND FIBRES.

Artificial silk; Weighting — and making it insoluble. A. Dubose. Soc. Ind. de Ronen, 1909, Sealed document No. 530.

TANNIN is added to the solvent used in making Chardonnetsilk. Thus the spun fibre contains tannin, and a

reducing substance is employed for the purpose of denitration, instead of ammonium sulphide, the base of this reducing substance uniting with the tannin to form an insoluble compound. Before denitrating, it is recommended that the fibre be passed through Turkey red oil. Substances which are recommended as reducers, are sulphides of magnesium, aluminium, antimony, tin, and silicon; magnesium, calcium, or aluminium hydro-sulphites or stannites, and tin chloride.

Silk fabrics; Analysis of natural and artificial —. Coppetti. Ann. Chim. analyt., 1909, 14, 47–51.

THE usual tests for distinguishing between natural and artificial silks frequently fail when the fabrics are weighted and dyed, and there are very few methods available for stripping the loading and dyestuff from the silk without destroying the fibre. The author has found that hydrofluoric acid is an excellent stripping agent, which readily removes the most refractory of the mineral loadings commonly employed. The fabric is steeped in hydrofluoric acid of the ordinary commercial strength for 5–10 minutes; it is then washed and heated in a solution of soap to the boiling point. It is washed again and placed in a 5 per cent. solution of hydrochloric acid with which it is boiled. Next it is bleached in a solution of sodium hypochlorite, again acidified, then washed and dried. An alternative method of bleaching, according to the nature and intensity of the dyestuff, consists in treating the fabric with a permanganate solution, followed by sulphurous acid. In this way the fibres are obtained practically free from mineral weighting and colouring matters, and the usual tests for the nature of the silk can be applied. When the fibres are sufficiently colourless, nitric acid is the best reagent for distinguishing between the silks of animal and those of vegetable origin; but if the residual colour is such as to mask the yellow stain produced by nitric acid, the fibres should be gently warmed on a glass slide with a 20 per cent. solution of potassium hydroxide, which dissolves the natural silks and the artificial silks which are composed of gelatin.—J. F. B.

Chlorinised wool. H. P. Pearson. J. Soc. Dyers and Col., 1909, 25, 81–83.

WOOL is chlorinised for use in the manufacture of underwear goods as follows:—Bleaching powder is dissolved in water to a solution containing 4 to 5 per cent. of available chlorine, and sodium carbonate solution is added in slight excess, the mixture being stirred, allowed to settle, and the clear liquor decanted. 100 galls. of bleaching powder solution containing 4.2 per cent. of available chlorine require 1 cwt. of 97 per cent. sodium carbonate. The resulting solution contains about 4 per cent. of available chlorine and has a sp. gr. of 1.09. The excess of alkali makes the subsequent liberation of chlorine more gradual. Solutions containing more than 4.5 per cent. of available chlorine are liable to form chlorate, which has a strong yellowing action on wool. From $\frac{1}{2}$ to 1 pint of the above-mentioned hypochlorite solution is required for each pound of wool, and a better handle is produced by adding this in two or three lots, acidifying after each addition, and running off after five or six minutes' treatment in each lot of acidified liquor. Hydrochloric acid is run in gradually to the extent of two-thirds of the volume of the hypochlorite solution for the first "end" and one-half for the second and third. The goods are well rinsed, and the colour is then restored by a bath containing 1 gallon of sodium bisulphite per 100 lb. of wool, a pint of strong sulphuric acid, previously diluted with water, being gradually run in. A bath of stannous chloride and hydrochloric acid may be used instead of the bisulphite bath. After rinsing again, the goods are scoured with soap and a very little sodium carbonate to restore the handle. It is essential that the acids should be run in very slowly; the goods must be kept moving, and occasionally squeezed, and the machine should be well covered in. Dry chlorine has no action on dry wool, and "moderately chlorinised" wool contains no chlorine, so that the expression is really a misnomer. The edges of the scales of the fibres are smoothed down by chlorinising, and the wool loses its felting property, and is therefore

almost universally employed in this condition for "guaranteed unshrinkable" goods. Chlorinised wool has much more affinity for direct dyestuffs than untreated wool, and it is possible to obtain colour effects by weaving the two together and then dyeing. For printing deep shades of black, and of some other colours, on woollen fabrics, it is necessary to first chlorinise the wool, though a lesser degree of chlorinising is employed for this purpose than for wool to be used for underwear. If a single drop of water is placed on chlorinised wool, it is fairly quickly absorbed, and the wet portion has a circular contour, whilst ordinary wool absorbs the drop very slowly and the contour of the wetted portion is irregular. Also wetted chlorinised wool has a characteristic seroop on rubbing. Comparative dyeing tests may also be used, or the fact that chlorinised and unchlorinised wool, when rubbed together, produce an electric charge sufficient to violently deflect the leaves of an electroscope. This phenomenon is not produced by two pieces of unchlorinised wool even though of different kinds. Garments of chlorinised wool wear badly.—E. F.

Adsorption (dyeing) and agglutination (felting) of the wool fibre. E. Justin-Mueller. Z. Chem. Ind. Kolloide, 1909, 4, 64—70.

THE author shows experimentally that the felting of wool is due to the swelling of the fibre, under the action of the bath, to form something very like a colloidal gel, and not to entanglement of the fibres by means of their scales, as generally supposed. This was shown by heating wool fibres with liquids whilst the fibre was rigidly fixed in the bath; scarcely any felting took place with distilled water at 100° C. in one hour; with water containing much lime, distinct felting was observed under the same conditions, whilst sulphuric acid also caused felting. The addition of a small amount of sulphuric acid diminishes the felting caused by lime in water, but it is again increased by addition of a further quantity. This felting of the fibre is not absolutely essential to dyeing. The behaviour of wool towards dyestuffs is shown to be quite different from that of wood- or bone-charcoal. Adsorption by the two latter is independent of the temperature, and of additions to the bath, whilst the wool-fibre only adsorbs the dyestuff at a temperature near the boiling point of the bath, and often only in presence of certain additions to it. Direct dyeing depends on the solubility coefficient of the dyestuff in the bath on the one hand, and on the adsorption-coefficient of the fibre under certain conditions on the other, and is a reversible phenomenon; if the former factor predominates, no dyeing takes place. The sulphuric acid used when dyeing with acid dyestuffs acts, according to the author, by lowering the solubility of the dyestuff in the bath; dyestuffs which are only slightly soluble in water do not require the addition of sulphuric acid. Basic dyestuffs, on the other hand, are more soluble in acid than in alkaline media, and therefore only dye very weakly from an acid bath. The high temperature which is necessary causes the fibre to swell, in which condition its adsorption-coefficient is sufficiently increased to overcome the solubility-coefficient of the bath.—E. F.

Paranitraniline Red; Formation of —. M. Prudhomme and A. Colin. Rev. Gen. Mat. Col., 1909, 13, 66—68.

HAVING previously shown (see this J., 1909, 87) that the best red is produced with a developing bath which contains free acetic acid and an excess of sodium acetate, the authors have now studied the effect of variations in the duration of the immersion, and in the concentration of this bath. They find that the intensity of the red produced is proportional to the concentration of the developing bath and to the duration of the immersion. The result is different when the bath contains a highly ionised acid (free hydrochloric acid for instance), for then the red does not develop until the pattern is placed in water and the shade (which is yellowish-red), is the more intense—or better, the less attenuated—the shorter the time of immersion. Given a prolonged immersion, the shade obtained is an orange-brown and the bath itself becomes coloured brown. The presence of the free acid retards the development of the colour and causes

the reaction to take quite a different course; β -naphthol is liberated and, being to some extent soluble in dilute acid, is dissolved and reacts in the bath with the diazo compound. The product, however, is different to that produced under normal conditions and can be isolated as an orange-brown powder. The conclusions arrived at are, that a good red is produced upon material which has been ground with either sodium naphtholate or free naphthol, by developing with a solution of a free diazo compound or its neutral salt. The presence of a highly ionised acid not only retards the development, by lowering the degree of ionisation of the diazo-compound, but brings about variations in the mode of combination and thus produces colours other than the red desired. Acetic acid, in equivalent proportions, does not affect the degree of ionisation of the diazo-acetate and acts but little upon the sodium naphtholate. The presence of sodium acetate hinders the diffusion of sodium naphtholate into the bath, diminishes the degree of solubility of naphthol in the acetic acid, and lowers the degree of ionisation of the acetic acid. These conditions are those which are most suitable to the production of a good red. The degree of blueness of the shade depends upon the amount of insoluble azo-colour deposited upon the fibre. The development of the colour should not occupy more than about 30 seconds, as longer contact with the diazo solution appears to injuriously affect the shade of red.—F. M.

Fastness of colours to light; Use of potassium ferriocyanide in determining the —. E. Bechtel. Rev. Gen. Mat. Col., 1909, 13, 73.

POTASSIUM ferriocyanide and ferriocyanide when in solution, are both decomposed by solar light, and the amount of decomposition varies with the concentration of the solution, the intensity of the light, and the duration of the exposure. In the absence of light the salts are quite stable. The decomposition is most rapid with the ferriocyanide and takes place according to the equation, $\text{Fe}_3(\text{CN})_{12}\text{K}_6 + 6\text{H}_2\text{O} = 6\text{KCN} + 6\text{HCN} + \text{Fe}_3(\text{OH})_6$; the concentration of the solution diminishes in arithmetical progression and the quantity of ferric hydroxide precipitated increases at the same rate. Using a solution containing say 50 grms. per litre, and placing this in hermetically sealed vessels so that no other influence but light can affect it, the amount of ferric hydroxide deposited will be a measure of the intensity of the light to which the solution was exposed. The dyestuff to be tested is dyed upon suitable material and the shade is exposed side by side with a solution of ferriocyanide, until it has faded to a definite extent, ascertained by comparison with a standard tint. The ferric hydroxide which has been precipitated from the ferriocyanide solution is then estimated and serves as a guide to the degree of fastness of the shade.—F. M.

Locust bean; The — and some of its practical applications. M. C. Lamb and F. J. Farrell. J. Soc. Dyers and Col., 1909, 25, 77—81.

THE seeds of the locust bean are removed from the pod, freed from the husks and germ, and then from the inner husk by grinding and "perlina." The two cotyledons remain, as small white discs. The gum is extracted from these by digesting with water under steam pressure for 48 hours. The gummy mass so obtained is strained through silk bags in a press, an antiseptic is added, and after setting, the product is sold as "gum tragacanth." After drying it contains:—Carbon, 43.51; hydrogen, 6.23; oxygen, 48.38; nitrogen, 0.39; and ash, 1.49 per cent. It absorbs a large quantity of water, but is soluble only to a very limited extent. The easiest way to prepare a "solution" is to stir well with hot water until the water is almost completely absorbed, heat gently, and add more water with stirring at 80° C. Gum tragacanth apparently enters into intimate combination with starches and fatty matters, and is a valuable sizing material. When a strong solution is allowed to set in a flat tray, a strong, almost transparent film is produced, which is very pliable and of great tensile strength; such films contain 60.5 per cent. of moisture. Gum tragacanth is also useful in the leather, laundry, and paper industries. Table linen may be sized with tragacanth, and can then be

passed through a multiple roll calender without any tendency to stick to the rollers. The great elasticity of a tragasol film renders the gum useful for dressing both the grain and the flesh sides of leathers, and when dyed leathers are treated in this way, the colours are rendered much faster to rubbing. It is more expensive than Irish moss and other mucilages used in leather dressing, but according to the authors, gives superior results. It is also more expensive than starch.—F. F.

Partial hydrolysis of proteins. Abderhalden. See XVIII.1.

PATENTS.

Weighting silk; Process of —. Wegmann et Cie. Fr. Pat. 394,696, Sept. 24, 1908.

THE silk is wound around hollow perforated bobbins, which are surrounded by perforated drums. This part of the apparatus is arranged within a circulating system through which the weighting solution, the washing liquor, etc., can be made to flow in the manner described in Fr. Pat. 335,596 of 1903 (this J., 1904, 251). The necessary liquor is forced into the interior of the bobbin, through its perforations, into the silk and through the perforations in the wall of the surrounding drum. If necessary, the drum can be replaced by a wrapper of cloth or other permeable material. The silk can also be dried in the hydro-extractor without unwinding it from the bobbins. —P. F. C.

Weighting process for muslins and other light fabrics. P. F. M. A. Durand. Fr. Pat. 395,188, Oct. 14, 1908.

THE fabric is immersed in a solution containing salts of aluminium and barium and afterwards in a second bath containing sodium sulphate, phosphate, or carbonate. The barium salt may be replaced by a soluble lead salt.—P. F. C.

Dyeing, washing, bleaching, etc., of textile materials; Apparatus for the —. H. Windrath. Ger. Pat. 206,401, Dec. 28, 1907.

THE patent relates to apparatus of the type in which the textile material is disposed in horizontal layers between perforated partitions, the dye-liquor, etc., being circulated through the layers, alternately in opposite directions, by means of a pump. According to the present specification the chamber in which the treatment is effected is divided by the horizontal perforated partitions into alternate material-compartments and liquor-compartments. The odd-numbered liquor compartments are connected to the suction-pipe and the even-numbered ones to the delivery pipe of a circulating pump, so that the liquid is forced through each of the compartments containing the textile material under identical conditions with respect to temperature, concentration, and pressure. Means are provided for reversing the direction of flow of the liquor. —A. S.

Vegetable fabrics; Process for stiffening and making impermeable —. L. S. Marix. Fr. Pat. 394,657, Aug. 28, 1908.

THE material is ironed or calendered, then immersed in a solution of celluloid, and finally dried in order to evaporate the solvent.—P. F. C.

Viscose; Process of applying and treating strands with —, and the article. L. M. Churier, Assignor to Soc. Franç. de la Viscose, Paris. U.S. Pat. 912,812, Feb. 16, 1909.

VII.—ACIDS, ALKALIS, SALTS, AND NON-METALLIC ELEMENTS.

Hypophosphorous acid; Catalytic oxidation of — by copper. J. Bougault. Compt. rend., 1909, 148, 415—417.

WHEN solutions of 8 grms. of copper sulphate and 2 grms. of sodium hypophosphite are mixed, a brownish-yellow precipitate falls which is converted on boiling into crystalline metallic copper. If the hypophosphite be in large excess (10 grms. to 2 grms. of copper sulphate), a brown precipitate is formed, no doubt Würtz's "copper hydride," which when heated evolves hydrogen and clots together on the surface of the liquid. This clot is without action on boiling water, but boiled in solution of sodium hypophosphite, evolves hydrogen and oxidises the hypophosphite to phosphite and phosphate. The action ceases before the whole of the hypophosphite is oxidised, but on decanting the solution and adding a fresh solution of hypophosphite, it begins again. In this way a considerable quantity of hydrogen can be obtained by means of a small amount of copper (1 atom of copper to about 30 molecules of hydrogen). Copper reduced by zinc also produces this effect, but much more feebly. Probably the fundamental reaction is the catalytic decomposition of water, the hydrogen of which escapes whilst the oxygen oxidises the hypophosphite.—J. T. D.

Bleaching powder; A crystalline —. K. J. P. Orton and W. J. Jones. Chem. Soc. Proc., 1909, 26, 74.

A BASIC hydrated compound of calcium chloride and calcium hypochlorite, which separates on cooling moderately concentrated (about 2N) solutions of bleaching powder, was described. This substance has been obtained in large, prismatic crystals, the properties of which closely resemble those of bleaching powder. On the other hand, from very highly concentrated solutions of bleaching powder (about 4N), a hydrated calcium hypochlorite separates at low temperatures.

Nitrites; The action of carbon dioxide on —. E. R. Marle. Chem. Soc. Proc., 1909, 26, 74.

THE contradiction in the results obtained by Marie and Marquis (this J., 1904, 252 and 369) and Meunier (this J., 1904, 321 and 56; see also Papasogli, Gaz. chim. ital. 1881, 11, 277; Moody, this J., 1903, 1352) in investigating the action of carbon dioxide on nitrites seems to be partly due to the unsuitability of potassium iodide and starch as a test for traces of nitrites unless special precautions be taken. Warrington (Chem. News, 1885, 51, 39) finds that one of the most delicate tests for nitrous acid is the coloration produced with α -naphthylamine (Griess).

Carbon dioxide prepared from marble and hydrochloric acid, was washed by passing through water in two Drechsel bottles, and was then passed through 10 per cent. aqueous potassium nitrite in a Cloez washing bottle, the construction of which is such that it is unlikely that liquid will be mechanically carried over by the stream of gas. It was then passed into water or potassium carbonate for periods varying from one to six hours. In every case the coloration with potassium iodide and starch seemed slightly greater than that produced by the reagents alone. With

α -naphthylamine, a faint pink coloration resulted after a few minutes. To guard against the possibility of mistaking nitrite, mechanically carried over, for nitrous acid, a dry Arnold absorption apparatus was inserted between the Cloez bottle and the final flask. A slight mist appeared on the inside of the absorption bulbs, which, when washed out with water, proved faintly acid to litmus, and with α -naphthylamine gave a full red colour, appearing in about three minutes. The water in the final flask was neutral (after boiling), and gave with α -naphthylamine a faint coloration, appearing in about fifteen minutes. From the data in Warrington's paper, the quantity of nitrogen (as nitrous acid) removed by one litre of carbon dioxide is probably less than one two-hundredth of a milligram. The reduction of very dilute potassium permanganate by the solution in the final flask leads to a similar figure.

Ammonium nitrite: Decomposition and sublimation of —.
P. C. RAY. Chem. Soc. Proc., 1909, 25, 56.

WHEN an aqueous solution of ammonium nitrite is heated in a vacuum at about 37 – 40°C ., only a very small portion of the salt decomposes according to the equation: $\text{NH}_4\text{NO}_2 = 2\text{H}_2\text{O} + \text{N}_2$; the main bulk of the salt crystallises out. If the temperature is then gradually raised to 70°C ., slow decomposition continually proceeds according to the above equation, but the major portion of the salt sublimes unchanged. When this sublimate is heated by means of a naked flame, the gaseous products are nitrogen and nitric oxide, the latter often amounting to as much as 6 per cent.

Ferrous sulphate solutions: Resistance of — to atmospheric oxidation. T. Warynski. Ann. Chim. analyt., 1909, 14, 45–47.

SOLUTIONS of pure ferrous sulphate, acidified with sulphuric acid, are by no means so readily oxidised on exposure to the air as was previously supposed. Dilute solutions ($N/50$) of acidulated pure ferrous sulphate were placed in large bottles, the stoppers of which were removed once a day, to renew the supply of oxygen in contact with the liquid. The solutions were standardised from time to time, and it was ascertained that after 4 months' exposure only about 1.0–1.4 per cent. of the original iron had been oxidised from the ferrous to the ferric state. At high temperatures (80° – 96°C .) the solutions were found to be equally resistant. The presence of sulphuric acid has a retarding action on the oxidation. The solutions mentioned above contained 0.45 gm.-mol. of sulphuric acid per litre; other solutions, containing similar quantities of iron with 0.5 gm.-mol. of sulphuric acid, showed, after 120 days, an oxidation of 0.5–1.0 per cent. of the iron salt present, whilst solutions containing 2 gm.-mols. of acid showed an oxidation of only 0.1–0.2 per cent. On the other hand, minute quantities of certain impurities are capable of accelerating the oxidation of the ferrous salt. When piano wire was dissolved in such proportions that the solution contained 0.27 gm.-mol. of ferrous sulphate and 1.42 gm.-mol. of sulphuric acid per litre, the oxidation at the end of 100 days amounted to 8.86 per cent. Cupric chloride induces a very rapid oxidation of the ferrous salt; with a concentration of 0.001 gm.-mol. of cupric chloride per litre, the oxidation after 120 days amounted to 41.8 per cent. Platinum chloride and palladium nitrate are still more active catalysts than cupric chloride. Hydrochloric acid at a concentration of $N/1$ – $N/2$ also intensifies the oxidation to a moderate extent. On the other hand, certain other salts, e.g. zinc sulphate, silver nitrate, nickel chloride, chromium sulphate, vanadium sulphate, and uranium acetate were found to be without effect.—J. F. B.

Nickel sulphide: Separation of — from aqueous solution. A. Thiel and H. Ohl. Z. anorg. Chem., 1909, 61, 396–412.

It has been observed (this J., 1908, 473) that ammonium sulphide fails as a delicate test for nickel in the presence of much ammonia. This is due to a delay in the separation

of the nickel sulphide which after a while becomes apparent as a brown solution. The speed of the reaction is found to increase with the concentration of the nickel salt or of the alkaline sulphide and also with rise of temperature, but it diminishes with an increase in the ammonia concentration. The authors reject the view that the phenomena are due to the formation of complexes in the ammoniacal solution, for the separation of nickel sulphide is also hindered, though not prevented, by the presence of acids, and in the presence of acetic acid a brown colour often develops, as in alkaline solution; moreover, other reagents behave normally with nickel salts in ammoniacal solution. They put forward the following explanation:—in ammoniacal solution the complex ion, $\text{Ni}(\text{NH}_3)_6^{++}$, is in equilibrium with nickel ions, Ni^{++} , and ammonia; the concentration of the nickel ions is therefore increased by a rise in the total nickel concentration and diminished by an increase in the ammonia concentration. On adding a sulphide, a primary (labile) equilibrium is established according to the equation, $\text{Ni}^{++} + \text{S}^{--} \rightleftharpoons \text{NiS}$, the concentration of the nickel sulphide molecules rising with that of the nickel ions or sulphur ions. This comparatively soluble nickel sulphide then polymerises to a less soluble form and separates as a colloid (brown liquid) or precipitate. In acid solution the concentration of the nickel ions depends merely on that of the nickel salt, and that of the sulphur ions falls with an increase of acidity which therefore hinders the separation of the sulphide. The rate of polymerisation is increased by rise of temperature.—F. SOEX.

Bismuth hydroxide and its behaviour towards alkalis.
L. Moser. Z. anorg. Chem., 1909, 61, 379–386.

BISMUTH hydroxide is obtained, free from basic salts, by adding a solution of a bismuth salt, containing glycerin, to caustic alkali solution, and then sufficient acetic or dilute nitric acid to leave the solution only faintly alkaline. The orthohydroxide, $\text{Bi}(\text{OH})_3$, is probably first precipitated, but this loses water very readily. In the presence of alkalis the orthohydroxide changes finally to the metahydroxide, $\text{BiO}\cdot\text{OH}$, which is fairly stable in air free from carbon dioxide; this changes in colour on exposure to light, from yellowish-white to grey, another modification of the metahydroxide being apparently formed. Bismuth hydroxide is practically insoluble in cold dilute alkalis (up to $N/1$), but is distinctly soluble in strong solutions. At 100°C the solubility in strong alkalis is quite considerable, and even in dilute solutions ($3N$ to $N/2$) it is not negligible.—F. SOEX.

Bismuth halides: Hydrolysis of —. W. Horz and A. Bulla. Z. anorg. Chem., 1909, 61, 387–395.

THE hydrolysis of bismuth chloride and bromide at 25°C . is found, under all conditions of experiment, to give only the oxy salts, BiOCl and BiOBr , the reactions strictly following the law of mass action. Bismuth fluoride is perfectly stable even in boiling water, undergoing no hydrolysis.—F. SOEX.

Solutions of colloidal sulphur and crystalloids: Experimental studies on a new system of equilibrium:—. T. Svedberg. Z. Chem. Ind. Kolloide, 1909, 4, 49–54.

SOLUTIONS of colloidal sulphur were prepared by a modification of Rafo's method, by dropping a strong solution of sodium thiosulphate into cold concentrated sulphuric acid. The liquid was diluted, filtered, precipitated with sodium chloride, and the colloidal sulphur repeatedly centrifuged and redissolved in water, until free from sulphate. The solution of colloidal sulphur so obtained shows in the ultramicroscope a cone of light, which is apparently homogeneous. The colloidal solution obtained as above always contains sodium chloride; in experiments with other electrolytes it was therefore freed from this by repeatedly precipitating with the electrolyte under examination and redissolving in water. It was found that for any particular concentration of electrolyte, a state of equilibrium was quickly reached, depending on the temperature, and that the amount of dissolved colloidal

sulphur increased with the temperature according to the exponential equation: $c = e^{kt}$ where c is the percentage of sulphur in solution, t the temperature, and k a constant which is a function of the molecular concentration of the electrolyte, and independent of the nature of the anion.

Colour reaction of ferrous salts. Richard and Bidot. See XXIII.

PATENTS.

Sulphur-burner; Agitating —. J. C. Wise, Watertown, N.Y. Re-issue No. 12,921, Feb. 16, 1909, of U.S. Pat. 835,926, Nov. 13, 1906.

THE burner consists of a stationery furnace surmounted by a secondary combustion chamber and partially encircled by a concentric receptacle or hopper in which the sulphur is melted by heat from the furnace. The molten sulphur passes into the furnace through feed-holes controlled by valves, and during its combustion it is stirred by a revolving stirrer, the shaft of which passes through the bottom of the furnace and is connected with mechanism below; residual impurities from the sulphur are forced by the agitator into a special aperture, normally closed by a plate, and may be removed as desired. Air is supplied radially towards the centre of the furnace through a number of adjustable inlets above the level of the material, so that the surface is uniformly supplied with air. The gases pass out from the furnace into the secondary combustion chamber above, in which is a transverse baffle-plate which becomes heated and so raises the temperature of the incoming gases preparatory to combustion, means being also provided for regulating the flow of the gases in a divided circuitous path around the baffle-plate and for admitting air through a number of adjustable inlets immediately above and below it. The capacity of the exhaust in the combustion chamber is also capable of adjustment.—F. SODN.

Sulphur dioxide; Process of making —. C. W. Lyman, New York. U.S. Pat. 911,735, Feb. 9, 1909.

MOLTEN sulphur is delivered in "a small stream" into a closed chamber where it is at once atomised by a jet of hot compressed air impinging on it. Additional heated air is introduced so as to maintain the proper proportion of oxygen in the chamber and secure continuous combustion of the sulphur to sulphur dioxide.—F. SODN.

Sulphuric acid; Process for the rapid preparation of — without employing a lead chamber. Erste Oesterr. Sodafabrik and C. Opl. Fr. Pat. 394,739, Sept. 28, 1908.

THE process is for the rapid production of sulphuric acid, without the use of lead chambers, by sending the gases containing sulphur dioxide through absorption vessels or towers in which they are oxidised by nitrated acid, the nitric oxide formed being reoxidised to nitrous acid and absorbed by sulphuric acid again. A series of 4–6 towers working systematically is preferably employed, a part of the gases circulating through the towers and part being compressed and utilised in elevating and pulverising the nitrated acid, so as to obtain intimate contact and rapid oxidation of the sulphurous acid; or, the apparatus for elevating and pulverising the acid may be actuated partly by the compressed gases and partly by air, and a concentrating tower, giving acid of 66° B., may be added to the system in order to utilise the heat generated in the process.—F. SODN.

Automatic draught regulator for use in sulphuric acid chambers. J. Gantier. Fr. Pat. 395,221, Dec. 21, 1907.

THE patent is for an automatic regulator of the draught at the exit of sulphuric acid chambers. It consists of a damper worked by water pressure, the supply of water for

this purpose being controlled by electro-magnets, the electric circuits for which are made or broken by a float moving in sympathy with the changes of pressure in the exit shaft. The pressure may be maintained constant within 0.1 mm. of water column.—F. SODN.

Hydrated sodium carbonate; Manufacture of —. W. F. Ridenour, Philadelphia, Pa. U.S. Pat. 912,622, Feb. 16, 1909.

HYDRATED sodium carbonate is made by mixing together sodium carbonate and water in such proportions that there is insufficient water to effect the crystallisation of the product; the mixture is stirred until cool. As an example, 500 lb. of soda ash would require 120–200 lb. of water.

—F. SODN.

Ammonia; Manufacture of —. J. Y. Johnson, London. From Badische Anilin und Soda Fabrik, Ludwigshafen, Germany. Eng. Pat. 2525 of 1909; date of application, Feb. 3, 1908.

AMMONIA is obtained by heating titanium nitride, or cyanonitride, with an acid (sulphuric or hydrochloric acid) or with the aqueous solution of a salt (aluminium chloride) from which acid is liberated, air being excluded and temperatures of 150°–200° C. being employed. (See Eng. Pat. 2414 of 1908, and Fr. Pat. 387,002; this J., 1908, 809.)—A. G. L.

Borax; Process of making —. G. E. Bailey, Assignor to A. Stevenson, Los Angeles, Cal. U.S. Pat. 911,695, Feb. 9, 1909.

NATIVE borates of calcium or magnesium, or other ores containing the borate of a metal capable of forming an insoluble sulphate, are roasted with sodium sulphate and the product leached with water. By cooling the liquor nearly to 0° C. borax is precipitated in a finely divided state.—F. SODN.

Cyanide briquettes; Process of making —. J. Bueh, Dessau, Germany, Assignor to The Roessler and Hasslacher Chem. Co., New York. U.S. Pat. 912,538, Feb. 16, 1909.

CYANIDE crystals are formed into briquettes which are then heated in a vacuum at about 70° C. so as to evaporate the water contained in them, without decomposing the cyanide.—F. SODN.

Hydrosulphites [hyposulphites] free from water and perfectly stable; Production of —. Badische Anilin und Soda Fabrik. Second Addition, dated Sept. 28, 1908 (under Int. Conv., Nov. 5, 1907), to Fr. Pat. 354,273 of May 13, 1905. (See this J., 1905, 673; 1907, 1091.)

ACCORDING to the present addition, the hydrated hydrosulphite, freed as far as possible from mother liquor, or the solution of a hydrosulphite, is dehydrated by evaporating to dryness, preferably under diminished pressure, in a current of ammonia gas, in which the hydrosulphite is stable.—F. SODN.

Phosphated salt [table salt]; Process of manufacturing —. G. Calvé. Fr. Pat. 394,678, Sept. 15, 1908. Under Int. Conv., May 7, 1908.

THE patent is for the process of making the phosphated salt known as "Gemme extra Calvé." Highly purified salt is finely ground and then very intimately mixed with pure, white calcium phosphate. The product does not agglomerate and is not hygroscopic; it is packed in tins lined with paper.—F. SODN.

Crystallised alumina; Process of making — from bauxite. A. Simon. Fr. Pat. 394,805, Sept. 30, 1908.

CRYSTALLISED alumina, equal in hardness to corundum, is obtained from bauxite by eliminating the silica with

hydrofluoric acid and the iron with chlorine or a chloride at a high temperature. For example, the crushed bauxite may be mixed with 10–20 per cent. of sodium chloride and heated to 1200–1400° C., hydrofluoric acid being led into the fused mass, or the mineral may be first treated with hydrofluoric acid in the cold. The heating is continued for 4–6 hours, until crystallisation is effected. It is necessary to employ only the calculated quantities of the reagents, or loss of aluminium may occur.—F. SOHN.

Hydrated alumina: Process of calcining —. A. Vergé. Fr. Pat. 395,142, Dec. 18, 1907.

The calcination of hydrated alumina is carried out in thin-walled vertical cylinders of refractory material, which are heated externally as in the firing of porcelain. The cylinders pass through the top and bottom of the heating chambers and are charged from above, before heating commences, and discharged, after calcination, by opening a valve at the lower end, when the material falls into a channel or conveyor situated beneath; a series of heating chambers is preferably employed. The advantages claimed for the process are: (1), there is no loss of material; (2), the wear and tear is much reduced; (3), the heat is fully utilised; (4), there is very little handling of the material. The purity of the product is equal to that attained by other processes.—F. SOHN.

Sulphur: Process of recovering — from sulphur-bearing gases. P. S. Smith, Assignor to The E. I. du Pont de Nemours Powder Co., Wilmington, Del. U.S. Pats. 912,743 and 912,744, Feb. 16, 1909.

The gases containing sulphur dioxide are mixed with water-gas, a continuous supply of which is secured by employing more than one generator. The mixed gases are heated by the combustion of the producer gas obtained as a by-product in making the water-gas, and sulphur is thus liberated by the reaction between the water-gas and sulphur dioxide.—F. SOHN.

Air and its elements: Process of separating — by fractional distillation. M. Hazard-Flamand. Fr. Pat. 394,881, Dec. 10, 1907.

The principle of the Savalle column is applied to the separation of the constituents of air. The air is first cooled to the temperature of its saturated vapour (–190° C.), partly in a heat interchanger and partly by expansion or in any other manner, and then passes into the column at the appropriate point; fractionation proceeds in the usual way, the reflux liquid at the top of the column being nitrogen, and liquid oxygen collecting at the bottom. The liquid oxygen is tapped off by a siphon into a jacket surrounding the boiler of the still, in which it is evaporated, this evaporation and the heating of the liquid in the still being effected by heat absorbed from a part of the nitrogen produced, which is cooled and compressed, and then, becoming liquefied, is returned at the top of the column as a reflux liquid. Or, the column may be surmounted by an auxiliary column, the gas issuing from the first serving to heat the boiler and evaporator of the second column, with or without the use of a dephlegmator; the liquid nitrogen thus produced is used as a reflux liquid in both columns. Auxiliary cooling of the apparatus is obtained by an external supply of liquid air or nitrogen, either supplied to the column itself or used to cool the air or nitrogen supply, or these may be cooled by previous compression and expansion.—F. SOHN.

Hydrogen: Production of —. Dellwik-Fleischer Wassergas-Ges. m. b. H. Fr. Pat. 395,132, Oct. 10, 1908.

The invention relates to the production of hydrogen by the action of steam on iron, with the alternate reduction of the oxide formed, the iron employed being prepared by the reduction of a mineral oxide which retains both porosity and resistance after repeated use. In order to prevent a deposition of carbon during the reduction of the iron oxide in the retort, the reducing gas is mixed

with a volume of steam equal to at least half the sum of the carbon monoxide and hydrocarbons present in it. It is also found economical to carry the reduction only half way, instead of completely to the metal, and this, moreover, gives purer hydrogen, since no carbon can be deposited during such partial reduction.—F. SOHN.

Alkali hydrosulphites: Manufacture of —. P. A. Newton, London. From Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. Eng. Pat. 11,865, June 1, 1908.

SEE Ger. Pat. 203,910 of 1908; this J., 1909, 90.—T. F. B.

Hydrosulphites: Manufacture of stable, anhydrous —. J. Y. Johnson, London. From Badische Anilin und Soda Fabrik, Ludwigshafen on Rhine, Germany. Eng. Pat. 20,199, Sept. 25, 1908.

SEE Second Addition to Fr. Pat. 354,273 of 1907; preceding.—T. F. B.

Hydrosulphites: Preparation of — in solution and in the solid state. Badische Anilin und Soda Fabrik. Second Addition, dated Sept. 28, 1908, to Fr. Pat. 293,192, Oct. 9, 1899. Under Int. Conv., Nov. 1, 1907.

VIII.—GLASS, POTTERY, AND ENAMELS.

PATENTS.

Ceramic objects: Manufacture of porous —. Grünzweig und Hartmann, Ges. m. b. H., Ludwigshafen, Germany. Eng. Pat. 22,613, Oct. 24, 1908. Under Int. Conv., May 9, 1908.

HIGHLY porous ceramic objects are obtained by mixing a combustible substance (e.g., cork), with the clay, etc., and burning in a kiln (preferably of the continuous type), to which steam and carbon dioxide, with or without oxygen or nitrogen, are admitted, so as to maintain therein a constant temperature.—A. G. L.

Porcelain or china-ware of low fusing grade: Manufacture of —. E. Berdel, Hôhr, Germany. Eng. Pat. 23,461, Nov. 3, 1908.

TRANSPARENT porcelain is obtained by mixing together 30 parts of kaolin, 5 of clay, 60 of felspar, and 5 of fluorspar free from iron, and burning at Seger cone 1 or 2. The addition of 0.1 part of "soda" renders the mass suitable for casting.—A. G. L.

Potteries, glass works, enamelling of metals, and similar industries: Plant [Furnaces] for —. F. Garros. Fr. Pat. 394,666, Sept. 5, 1908.

IN order to raise the temperature of the furnace rapidly, the door is movable, and channels are provided in the

thick part of it, for the circulation of hot or burning gases. There is also a box-saggard with double walls, between which a layer of air is enclosed. In the case of furnaces in which the saggars are surrounded on all sides by fire-holes, the heat of the combustible is utilised to the most complete extent, a fire-hole being arranged in the thick part of the door, and the products of combustion passing round suitable channels, by which the air-supply for the grates enters, in such a way that the air can be preheated, as desired, before passing through the fuel.

—W. C. H.

Window glass; Machines for the continuous drawing of — by means of a vacuum. H. D. Hershey, Fr. Pat. 394,873, Sept. 28, 1908. Under Int. Conv., Jan. 22, 1908.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

Portland cement: Influencing the physical properties of — by fine grinding. R. K. Meade. Tonind.-Zeit., 1908, 32, 2184—2187.

FINE-grinding generally has the effect of making a cement quicker in setting, sometimes to such an extent as to render the product useless; but this effect is much more marked with a cement rich in clay than with one rich in lime and lightly burnt, and with a well-proportioned cement only a slight increase in the speed of setting should result from finer grinding. The tensile strength of pure unmixed cement is reduced by fine-grinding, but that of the same cement, mixed with sand, is increased, as is seen in the following tables, which show the tensile strength in kilos. per sq. cm.

Residue on sieve of 5000 meshes
per sq. cm.

2 years ...	59-76	39-37	29-88	44-99

It will be seen from the first table that for use with sand, 25 per cent. less cement is required, when the residue is reduced from 20 to 10 per cent., and the author estimates the extra cost of milling at 37 per cent., but as only 15—20 per cent. of the cost price of the cement represents the grinding of the clinker, the cost per barrel would

only be raised from 1 to 1-06 dollars. But fine-grinding brings no advantage, unless there is a corresponding increase in the percentage of impalpable powder or "flour," on which the setting properties of cement depend, and unfortunately sifting gives no idea of the relative merits of different types of mill in this respect. For instance, a sample of cement made to pass completely through a sieve with 5540 meshes per sq. cm., by repeatedly sifting and regrinding the residue, when mixed with sand showed no tensile strength after 7 days or even 3 months, but the same cement ground without sifting, until a residue of 23-5 per cent. was obtained with the same sieve, showed with sand, at 7 days, a tensile strength of 15-11 kilos., and at 3 months, 22-8 kilos. per sq. cm. The soundness of a cement is also affected to some extent by fine grinding, and a cement otherwise unsound can sometimes be made to pass the boiling test by attention to this point.—F. SOPX.

Portland cement; Influence of fine-grinding on the physical properties of —. E. Riisager. Tonind.-Zeit., 1909, 33, 258—260.

REFERRING to the work of Meade (see preceding abstract), it is pointed out that the effects of fine-grinding are specially noticeable in the cements cited, because, presumably, they were made in rotary kilns, and that thorough grinding is of great importance with cement made in this way. But it is urged that more attention should be given to the choice of a suitable type of mill, which will give the largest proportion of flour in the product, than to extra fineness of grinding, with its accompanying expense, though it is admitted that fine-grinding should be aimed at. Tube-mills are regarded as superior to ball-mills; for, by the use of a ball-mill and separator, much power is wasted, because the latter separates but a small proportion of the flour, returning most of it to the mill, which means that the same material goes through the separator and elevator many times and causes needless wear and tear, and moreover the product is inferior in the proportion of flour to that obtained with a mill in which no sifting or separation takes place during milling. Attention to the proportion of flour is of equal importance in grinding the raw materials, especially where these are hard, and an instance is cited in which it was found impossible to obtain a sound cement, when the raw materials were ground with a so-called sieveless ball-mill, though by substituting tube-mills, satisfactory results were obtained.—F. SOPX.

PATENTS.

Colouring and impregnating wood: Process for —. C. F. Brineker, jun., Copenhagen. Eng. Pat. 6538, Mar. 24, 1908.

SOLID extract of campeachy is dissolved in 10—20 times its weight of water and the wood to be impregnated is treated first with this solution under steam pressure and afterwards with a solution of iron acetate, care being taken that the wood does not absorb more of the iron solution than can be fixed by the absorbed campeachy extract. The wood is next dried at 25° C., then treated with a 15 per cent. soap solution which has been warmed slightly, again dried, and finally treated with a shellac solution to prepare it for polishing.—P. F. C.

Marble, granite, and similar materials: Process for the manufacture of artificial —. H. Jakobi. Fr. Pat. 394,688, Sept. 21, 1908.

THE moistened raw materials are worked up in a cylinder, provided with a screw, whereby the mixture is forced through the perforated bottom of the vessel in the form of small threads, which soon break off and fall on to an oscillating board or conveyor. The mixture is then sprayed with a liquid colouring material and fed into a cylindrical mixer, in which it is thoroughly worked up, and at the same time dusted over with a dry colour. The mixer is provided with an endless screw which drives the contents to the discharge end. The mixture can then be formed into the required shapes.—W. C. H.

Rotary and like kilns or furnaces [for cement, etc.]; Firing of —. A. Wilson, Doxey, Staffs. Eng. Pat. 1123, Feb. 24, 1908.

THE rotary kiln is heated by producer gas, blown into the lower end of the kiln together with air, previously heated to a high temperature by a reversible regenerator of firebrick or metal constructed so that it can be readily cleaned from dust. The regenerator may be inserted between the upper end of the kiln and the drying cylinder, or between the latter and the chimney. —A. G. L.

Hydraulic binding agents; Process for the preparation of — by the steam process. Zementfabr. Steinschal Max Reiche. Ger. Pat. 205,083, Feb. 7, 1907.

FINELY-DIVIDED cement-forming oxides, hydroxides, or salts (e.g., silicates) are mixed with slaked lime in proportions suitable for the production of cement, and the mixture is subjected to the action of superheated steam in presence of water. Or, the reaction-mixture may be composed of acid or neutral salts of cement-forming acids, together with a sufficient quantity of calcium hydroxide to yield products containing the groupings, $(-OCa)_2O$ or $(-OCa)(-OR)O$. The binding-agents thus obtained may be roasted in order to produce cements, or they may be used in the manufacture of artificial stone from materials such as quartz. —A. S.

X.—METALS AND METALLURGY.

Iron-carbon; Equilibrium diagram of the system —. H. M. Howe. Metallurgie, 1909, 6, 65—83, 105—126.

AFTER giving definitions of some terms used by him, the author discusses the merits of Roberts-Austen's diagram of the iron-carbon system as against the older diagram of Roozeboom, and cites the arguments for and against the view, deduced from Roberts-Austen's diagram, that graphite represents the stable and cementite the labile form of carbon. The correctness of this view is proved, because (1), the transformation of cementite into graphite is an exothermic reaction; (2), this transformation takes place in spite of the increase in pressure due to the greater volume occupied by the graphite formed; (3), on introducing carbon into iron, cementite is generally formed before graphite, in accordance with the general rule that of two bodies the less stable is first formed and then passes into the more stable. In addition, the direct transformation of cementite into graphite has often been proved microscopically to take place, but never the reverse; moreover, in making malleable cast-iron, cementite is transformed into graphite, often in quantity exceeding the saturation point (2.2 per cent. of carbon) of austenite. The author further discusses a number of points arising out of the diagram in great detail. —A. G. L.

Steel for motor-cars. H. C. L. Holden. "Times" Eng. Suppl., March 10, 1909.

THE various steels used for motor-car construction may be conveniently divided as follows:—(a) Carbon steel containing from 0.12 per cent. to 0.2 per cent. of carbon; (b) carbon steel containing from 0.25 per cent. to 0.4 per cent. of carbon; (c) carbon steel containing over 0.4 per cent.; (d) nickel steel containing from 3 per cent. to 4½ per cent. nickel; (e) nickel steel containing from 4½ per cent. to 6 per cent. nickel; (f) nickel steel containing from 25 per cent. to 30 per cent. nickel; (g) chrome steel, containing up to 0.3 per cent. chromium; (h) silicon steel, containing from 1 per cent. to 1.3 per cent. silicon; (i) vanadium steel, containing from 0.25 per cent. to 1 per cent. vanadium; (j) nickel chrome; (k) nickel vanadium.

The first class of steel (a) is that which is known as mild steel, it can be forged and welded without much difficulty; it is soft and readily machined, and it can be bent cold and treated much in the same way as wrought

iron, without apparent deleterious effect. When case hardened, it is extremely useful for parts where surface hardness is required as a prime factor, and not strength.

Of alloy steels, nickel steel would appear to be the most important. The addition of nickel to ordinary carbon steels, when the amount is greater than 1 per cent. and does not much exceed 6 per cent., has the effect of not only hardening the steel but of also increasing its elastic limit very materially—by approximately 3 per cent. for each 1 per cent. increase of nickel, and its ultimate strength in the same way by about 4 per cent.; it also renders the steel less susceptible to fracture by shock and by alternations of stress. These favourable conditions, however, can only be obtained by suitable thermal treatment of the material, but when this is done such steel may be considered as perhaps more reliable than any other.

A nickel steel containing 0.3 per cent. of carbon and 3 per cent. of nickel has approximately the following mechanical properties:—Elastic limit, 28 tons per square inch; ultimate strength, 42 tons per square inch, with an elongation of 20 per cent., and if thermally treated and oil hardened these can be raised to 35 and 55 with a slight reduction in the elongation. These figures can, by different proportions of carbon and nickel, be somewhat increased, but at the expense of the ductility.

Class (h) shows apparently the best proportion of nickel that can be employed where high elastic limit and strength are the qualities desired, without too much sacrifice of ductility. Generally, as the ultimate strength goes up the elongation goes down, and in the present state of our knowledge it may be said that the carbon in nickel steel should not exceed 0.5 per cent. nor the nickel 6 per cent. if the material is to be reliable. By far the greater proportion of nickel steel used for motor-cars is of the 3 to 3.5 per cent. nickel content.

(f) This is an interesting class of nickel steel which has its own peculiar uses. It contains about 0.12 per cent. carbon and from 25 to 30 per cent. of nickel. It is very little affected by high temperatures, up to bright red heat; it does not oxidise, and though not very strong, having an ultimate strength of only 36 tons, yet its elongation at the breaking point is something like 36 per cent. These properties make it very suitable for exhaust valves, for which purpose it has been somewhat widely employed by the best Continental makers.

(g) Chromium has a very distinct property of increasing the intrinsic hardness of carbon steel, but unfortunately by itself it renders the material somewhat brittle.

(h) is a somewhat interesting alloy which has been employed on the Continent to a considerable extent for gear wheels and springs. For the former purpose the proportion of silicon may reach 3 per cent., and with a comparatively low carbon content, steel is obtained which, though perhaps hard to machine, is extremely resistant against wear, and attains a fine surface. These properties are improved by thermal treatment at moderate temperatures which do not induce warping of the article. For springs the percentage of silicon ranges from 1 to 1.3 per cent. or thereabouts, and the carbon from 0.7 to 0.5 per cent., the low silicon taking the higher carbon and *vice versa*. An elastic limit of 55 tons per square inch and an ultimate strength of 70 tons per square inch, or more, may be expected from such material when tempered for a spring. It has one characteristic which is required for springs, and that is its resistance to shock, which is very high when the other figures given above are taken into account.

(j) The alloy known as nickel chrome steel seems to possess both the qualities of nickel steel with the advantages of chrome steel, but without the disadvantages of the latter, provided that the amount of chromium is kept small, generally under 1 per cent. The hardness given by the chromium tends to raise the elastic limit nearer to the ultimate strength without affecting the toughness of the material. This steel is subjected to a case-hardening process to increase the carbon content on and near the surface, and is then heated and cooled, becoming extremely hard without any quenching whatever, thus combining all the qualities that are required for many parts of the engine and transmission of a motor-car, which necessitate

accuracy in dimension, hardness, toughness, and the greatest resistance to wear.

(i) (k) are alloys containing vanadium. When alloyed with carbon steel only, vanadium does not appear to the same advantage as it does when employed in conjunction with chromium and nickel chromium. The percentage of vanadium used is generally very small, under 0.2 per cent.

Platinum; Melting-point of —. C. Féry and C. Chêneveau. *Compt. rend.*, 1909, **148**, 401–404.

PLATINUM wires were melted by the electric current, by a Méker burner with an air-blast, and by the oxy-coal-gas blowpipe, and the melting-points determined by an optical pyrometer, allowance being made for the difference between the platinum and a black body. The temperatures registered were:—With the electric current, wire horizontal, 1690° C.; wire vertical, 1710° C. With the Méker burner and blast, 1740° C. With the oxy-coal-gas blowpipe, 1700°–1750° C., according to the oxidising or reducing character of the flame. The differences are largely due to the nature of the atmosphere surrounding the melting metal.—J. T. D.

Cuprous oxide in copper; New method for the determination of —. G. Coffetti. *Gaz. chim. ital.*, 1909, **39**, I., 137–143.

THE method is based on the fact that ammonia solution, in absence of air, will dissolve cuprous oxide but not metallic copper. The apparatus used is shown in the figure. A weighed quantity of the sample of copper, in the form of bright turnings, is introduced into the apparatus, on to a layer of glass-wool therein. The bent side tube is connected with a supply of hydrogen, which is passed through a strong solution of ammonia before entering the apparatus. When the air in the apparatus has been completely displaced by hydrogen, ammonia solution is run in from the tap-funnel. The whole is then allowed to stand until the colour of the solution does not appear to become deeper, whereupon the

liquid is run off through the small siphon, and the copper washed several times with a 10 per cent. solution of ammonia in recently boiled water. A further 50 c.c. of strong solution of ammonia is now introduced and the apparatus left for 4 or 5 hours, this series of operations being repeated until the strong ammonia solution is no longer coloured after contact with the copper for 4–5 hours. The ammoniacal solution of cuprous oxide is acidified with nitric acid, and the copper determined by electrolysis. Examples are given showing the accurate results obtained by the method.—A. S.

Copper and nickel; Process of treating magnetic pyrites containing —. Warlimont. *Metallurgie*, 1909, **6**, 83–92, 127–134.

SMALL working-scale experiments for the extraction of copper and nickel from magnetic pyrites were made on an ore containing 25.25 per cent. of sulphur, 42.40 of iron, 0.75 of copper, 3.10 of nickel, and 13.11 of silica. The ore was crushed so as to pass a sieve with 50 meshes per inch, and roasted, in lots of 5 kilos. at a time, in a small rotating horizontal kiln. The roasting was carried out for 8–10 hours at 480° C., and then for another 2–4 hours at 550° C. The gases given off contained up to 9 per cent. of sulphur dioxide. Two such intermittent kilns might be combined with one sulphuric acid plant: in a continuously working kiln the proper regulation of the temperature would be too difficult. The roasted ore contained up to 96 per cent. of the copper present in a form soluble in water, together with about 10 per cent. of

the nickel (and cobalt) and a considerable quantity of iron. It was exposed to the air in a moist state, this process of oxidation increasing the quantity of soluble copper slightly, and diminishing that of soluble iron considerably (to about half that of the copper), whilst the nickel remained practically unaffected. The oxidised ore was extracted with water, and washed two or three times with fresh water. From the solution obtained, copper was precipitated by means of scrap iron; iron was next removed by adding lime and blowing in air, and nickel (and cobalt) were finally precipitated by adding more lime. Or else, if but little cobalt was present, iron and nickel were precipitated together by means of lime, and the dried precipitate was added to the leached ore. This leached ore was next smelted for a crude nickel matte containing 45–50 per cent. of nickel, in an electric furnace, or in a reverberatory furnace. It might be necessary to add pyrites to bring up the sulphur content of the ore to 3 per cent., especially when using a reverberatory furnace. The slag obtained contained 0.23 per cent. of nickel. One H.P. year should suffice to smelt 25.5 tons of the ore. The crude nickel sulphide so obtained was next concentrated in a Bessemer converter, and the nearly pure nickel sulphide was cast into plates, which were used as anodes in the final electrolytic process. The cathodes consisted of sheets cut into the form of tridents, so that the anode surface was 2½ times the cathode surface. A current density of 60 amperes per sq.m. of anode surface was used, as with this density the cuprous sulphide in the anodes was oxidised only to cupric sulphide, thus leaving half the copper present (about 1 per cent. on the nickel) insoluble. The copper in the electrolytic nickel obtained could be still further decreased (to about 0.2 per cent.) by circulating the electrolyte, heated to about 60° C., through a vessel containing powdered nickel.

Incidentally, it was found that ferrous sulphate, heated in a current of air for 3 hours, was slightly decomposed at 460° and completely at 550° C. With copper sulphate the same treatment gave slight decomposition at 610° and complete decomposition at 650°. Nickel sulphate, containing 2.1 per cent. of free acid, was slightly decomposed at 500°, and almost completely at 670° C.—A. G. L.

Monel metal. D. H. Browne. *Electrochem. and Met. Ind.*, 1909, **7**, 114–115.

MONEL metal is a silver-white, nickel-copper alloy prepared from the nickel ores of Sudbury, Canada (see this J., 1909, 94). It contains 68–72 per cent. of nickel, 0.5–1.5 of iron, 0.014 of sulphur, and 0.073–0.15 of carbon, the remainder being copper. Its properties are profoundly influenced by the proportion of carbon and other impurities it contains, and the thermal treatment to which it is subjected. It melts at 1350° C., can be rolled between 900° and 1200° C., and annealed above 875° C.: the sp. gr. of the cast metal is 8.86–8.87 and of the rolled metal, 8.94–8.95. When rolled it becomes coated with a film of oxide, and is then very resistant to acids. The mechanical properties of the alloy are shown in the following table:—

	Cast metal.		1-in. Rods, as rolled.	1-in. Rods rolled, annealed, and cold-drawn.	1-in. Rolled plates.
	Grade C.	Grade D.			
Tensile strength ..	70,000	85,000	100,000	110,000	90,000
Elastic limit	27,000	40,000	50,000	80,000	45,000
Elongation, 2 ins.	30 %	25 %	30 %	25 %	30 %
Reduction of area	35 %	25 %	50 %	50 %	60 %

The rolled metal can be drawn into wire of all sizes down to 0.004 inch. The alloy should prove especially useful for the manufacture of seamless tubes for condensers and boilers for automobiles and motor-boats. Large castings can also be made of the alloy, which is much stronger than manganese bronze or Tobin bronze.—A. S.

Tin exports from the Federated Malay States. Board of Trade J., March 4, 1909. [T.R.]

THE weight of block tin and tin ore (tin exported in the form of ore having been taken at 70 per cent. of the gross weight of the ore) exported from the Federated Malay States during each of the years 1907 and 1908 was as follows:—

State.	1907.			1908.		
	Tin.	Tin contained in tin ore.	Total.	Tin.	Tin contained in tin ore.	Total.
Perak	tons.	tons.	tons.	tons.	tons.	tons.
Selangor	5,908	19,770	25,678	4,685	23,220	27,905
Negri Sembilan	4,886	11,417	16,303	2,184	14,632	16,816
Pahang	2,393	2,993	4,486	1,131	2,690	3,821
	751	1,224	1,975	784	1,569	2,353

Iron and steel; Corrosion of —. A. Sang. Proc. Engineers' Soc., W. Pennsylvania, 1909, 24, 493. 561.

PATENTS.

Reverberatory and like furnaces. A. I. Boulton, London. From E. Schmatolla, Berlin. Eng. Pat. 3394, Feb. 14, 1908.

At the front end of the hearth, *h*, of the furnace, is a vertical combustion chamber, *a*, which is supplied with gas from the producer, *g*, through the conduit *b*, and with heated air from the regenerator, *R*, by the conduit, *f*, and the openings, *c*, *d*. The air enters the regenerator at *f*, and becoming heated, enters the combustion chamber under a plus pressure. The gas from the producer also enters the combustion chamber under a plus pressure. If a reducing flame is required, the air is allowed to enter through the port, *c*, above the gas, the ports, *d*, being closed. If an oxidising flame is required, the port, *c*, is closed and the ports, *d*, are opened, the air entering below the gas.

W. H. C.

Iron from finely divided ores; Improvements in and apparatus for the production of —. P. M. Pritchard and The United Alkali Co., Ltd., Liverpool. Eng. Pat. 6561, Mar. 24, 1908.

FINELY divided iron ores are mixed with carbonaceous material and fluxing agents, and fed into the upper end of an inclined rotary kiln lined with refractory material. From this kiln the material, in a more or less reduced and fluxed condition, falls into a stationary bath-chamber, adjacent to the lower end of the kiln. Preheated air and solid powdered fuel are blown into this chamber so as to produce a non-oxidising flame in the chamber and kiln.

The reduced iron and slag are drawn off from time to time, either through tap-holes, or by tilting the bath-chamber. —A. G. L.

Cyanide, alkaline and other solutions; Apparatus for separating — from slimes, sand, and the like. G. H. Rayner, London. From Innes, Procter, and Hayles, Tarkwa, West Africa. Eng. Pat. 11,008, May 21, 1908.

THE mixed slimes and solutions are admitted intermittently from a hopper through a hollow shaft into a bottomless rotating basket, consisting of suitable filtering material (cotton or metal screen, etc.) secured between an outer perforated cylinder or cone and an inner one of vertical bars or wires. The material falls on to a rotating "impeller," provided with top and bottom plates, between which are placed blades which throw the material against the inside of the filtering medium, the liquid passing through into an outer chamber, whilst the solid particles adhere to the inside of the basket. From time to time the supply of material to the basket is stopped, and the solids adhering to the inside are removed, either by mechanical scraping, or by means of air or water delivered under pressure from jets placed close to the inside of the basket. The filtering medium, owing to the vertical inner bars, is never completely cleaned, and is thus protected from the full abrasive action of the next batch of solids projected against it.

—A. G. L.

[Thorium] ores; Art of treating —. R. McKnight, Pittsburg, Pa. U.S. Pat. 912,485, Feb. 16, 1909.

THORIUM ores are treated with a large excess of an alkali chloride. The mixture is heated until volatile and soluble chlorides of thorium have been formed, the vapours being condensed. The residue whilst still hot, is passed into water, and then through a pulveriser through which water is circulated. The same quantity of water is used for successive extractions, until it becomes supersaturated with and deposits thorium compounds, leaving the alkali chloride in solution, which may be used for the treatment of fresh ore. —A. G. L.

Pyritic smelting. J. T. Carriek, Assignor to B. S. Pattison, Johannesburg, Transvaal. U.S. Pat. 912,540, Feb. 16, 1909.

MEANS are provided for injecting into the furnace, flame blasts, giving off substantially neutral combustion products, immediately below the regular air tuyères and preferably intermediate thereof, in order to produce a restricted zone of higher temperature at the base of the "focus region" of slag formation. —F. SOPK.

Flue-dust in blast furnaces; Method of effecting the precipitation of — and of preventing the formation of the same. R. W. H. Atcherson and W. Siddall, Bellaire, Ohio. U.S. Pat. 912,641, Feb. 16, 1909.

JETS of a "dust-dampening agent" under high pressure are directed into the blast furnace throughout the whole of the gas zone. —A. G. L.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

(A.)—ELECTRO-CHEMISTRY.

Destruction of organic matter. Miorandi. See XXIII.

PATENTS.

Organic products; Process for the reduction and oxidation of — by electrolysis. H. Chaumat. First Addition, dated Dec. 19, 1907, to Fr. Pat. 393,561, Oct. 29, 1907 (this J., 1909, 148).

THE addition relates to the extension of the main patent to the reduction of substances in solution, and in particular to the reduction of sodium bisulphite in aqueous solution for the production of sodium hydrosulphite. A layer of coarse material is placed below the mass of powdered graphite with which the liquid is mixed, and the latter is drawn off from the bottom of the vessel, the material below acting as a filtering medium.—B. N.

Electrode for electric accumulators with alkaline electrolytes. Nya Akkumulator Aktiebolaget Jungner. Fr. Pat. 395,138, Oct. 10, 1908.

AN electro-active mass, consisting of finely divided metals, as iron, lead, etc., or of oxides or hydroxides of nickel, copper, silver, etc., is introduced in a suitable manner into the pores of artificial graphite. For instance, the latter is immersed in a solution of a salt of the metal in alcohol, or other convenient solvent, and by heating or by treatment with suitable reagents, the required electro-active mass is obtained and the solvent evaporated.—B. N.

Furnace, heated electrically by means of a resistance material composed of small fragments, for melting and boiling, especially for determining melting and boiling points. A. Deckert. Fr. Pat. 395,158, Oct. 12, 1908.

A CIRCULAR electrode fits into the bottom of an outer vessel of refractory material, and within the latter is placed a cylinder of similar material, into which is fitted a series of thin-walled refractory cylinders. Between these

and the inner crucible is placed the resistance material, a ring electrode slipping over the crucible and making contact with the resistance material. The height of the latter may be varied, as also the transverse section of the mass by the withdrawal of one or more of the cylinders, or, instead of these, a series of cylinders of different internal diameters, interchangeable with the cylinder fitting into the outer vessel, may be employed.—B. N.

XII.—FATTY OILS, FATS, WAXES, AND SOAPS.

Butter fat, coconut oil, and their fatty acids; The distillation of —. K. S. Caldwell and W. H. Hurtley. Chem. Soc. Proc., 1909, 26, 73.

BUTTER fat, coconut oil, and their fatty acids were distilled in the vacuum of the cathode light. The lowest fraction obtained from butter fat distilled with the bath temperature at 250–270° and inner thermometer at 187–210°. Tributyrin distils rapidly with the bath temperature at 127° and inner thermometer at 107°. For this and other reasons, it is concluded that butter does not contain tributyrin. The iodine values yielded by the various fractions seem to indicate that there is little or no triolein in butter fat. Lauric acid forms at least 60 per cent. of the fatty acids in coconut oil, whilst it could not be detected in butter; this method of distillation enabled the authors to detect with ease the presence of 10 per cent. of coconut oil in butter. The presence of palmitic acid in coconut oil has been questioned by Ulzei (this J., 1899, 1133), but the authors isolated several grams of this acid from coconut oil.

Cottonseed products: Rapid determination of oil in —. C. H. Heity, F. B. Stem, and M. Orr. J. Ind. and Eng. Chem., 1909, 1, 76–81.

Cottonseed meal.—40 grms. are extracted with 100 c.c. of carbon tetrachloride in a 250 c.c. flask at about 60° C. for at least 15 minutes, the liquid cooled to the ordinary temperature, shaken, and the whole strained through wire gauze on to a folded filter, the clear extract being collected in a graduated tube. The tube is cooled to the ordinary temperature, and the specific gravity of the extract is then determined. The specific gravity found is deducted from that of carbon tetrachloride at the same temperature, and the difference divided by 0.00286 gives the percentage of oil. It was found that between 15 and 30° C. the sp. gr. of carbon tetrachloride decreases by 0.0018 for each rise of 1° C. The values for carbon tetrachloride adopted are: 15°, 1.6041; 20°, 1.5951; 25°, 1.5861; and 30° C. 1.5771. If the carbon tetrachloride used in the analysis has a different specific gravity, the difference must be added to, or deducted from, the observed sp. gr. of the extract, as the case may be. *Hulls.*—10 grms. of the hulls, freed from whole seed, are treated just as in the case of meal, except that it is not necessary to strain through wire gauze. *Meats or kernels.*—10 grms. of the sample are used and the values obtained are multiplied by four. *Seed.* The sample is crushed and passed through a "meat chopper." 40 grms. are used with 200 c.c. of carbon tetrachloride and the values obtained are multiplied by two.—A. S.

Rape oil: Phytosterols in —. A. Windaus and A. Welsch. Ber., 1909, 42, 612–616.

WINDAUS and HAUTH (this J., 1907, 69) separated the crude phytosterol from Calabar beans into stigmasteryl and sitosterol. In linseed oil (this J., 1907, 1150) only sitosterol was found. On the other hand, Matthes and his collaborators (this J., 1908, 632, 818) found in cacao butter and cocoanut oil a mixture of phytosterols behaving towards bromine like stigmasteryl and sitosterol. The authors have found that the crude phytosterol of rape oil consists of a mixture of substances resembling stigmasteryl and sitosterol. The acetylated crude phytosterol yielded an insoluble tetrabromide, the composition of which agreed with the formula, $C_{30}H_{48}O_2Br_4$. The alcohol, for which the name of *brassicasterol* is suggested, was prepared from the acetate. It crystallised in hexagonal plates (m.p., 148° C.) containing one mol. of water of crystallisation ($C_{30}H_{46}O + H_2O$). Its specific rotation was $[\alpha]_D^{18} = -64.25$, or considerably higher than that of stigmasteryl ($[\alpha]_D^{18} = -45$). Brassicasteryl acetate formed thin hexagonal flat crystals melting at 157–158° C. The propionate melted at 132° C., and the benzoate (crystalline needles) at 167° C., whilst stigmasteryl propionate melted at 122° C., and the benzoate (rectangular plates) at 160° C. The phytosterol resembling sitosterol, which was separated from the filtrate from the brassicasteryl acetate tetrabromide, melted at 142° C. (sitosterol, 136–137° C.), and had the probable composition, $C_{27}H_{46}O$. Its acetate melted at 134° C., and its propionate at 116° C.—C. A. M.

Elaeostearic acid: Constitution of —. R. Majima. Ber., 1909, 42, 674–680.

KAMETAKA (this J., 1903, 1138) obtained the same tetrabromide and tetrahydroxy acid (sativic acid) from elaeostearic acid as from linolic acid, and therefore concluded that the two acids were isomeric. To obtain further information of the constitution of elaeostearic acid, the author has used ozone as an oxidising agent in a similar manner to that employed by Harnes and Türk (this J., 1906, 1158) with oleic acid. He has found that elaeostearic acid absorbs 2 mols. of ozone, which supports the view that it contains 2 double linkages. The di-ozone was an amorphous yellowish, semi-solid substance with the composition, $C_{18}H_{22}O_6$. When boiled with water it was readily decomposed, the products of decomposition including *n*-valeric aldehyde, *n*-valeric acid, the semi-aldehyde of azelaic acid, and azelaic acid. A substance that appeared to be succinic di-aldehyde was isolated, but neither succinic acid nor its semi-aldehyde could be identified,

and if present could only have been there in small quantity. The nature of the decomposition products supports Maquenne's view that elaeostearic acid contains double linkages between the fifth and sixth and the ninth and tenth carbon atoms as represented in the formula— $CH_3(CH_2)_3CH:CH(CH_2)_2CH:CH(CH_2)_2CO_2H$. The elaeostearic acid prepared from tung oil by Kametaka's method distilled almost unchanged in a current of carbon dioxide at about 225° C. under a pressure of 12 mm., leaving in the flask an amorphous (probably polymerised) residue amounting to about $\frac{1}{2}$ to $\frac{1}{3}$ of the original substance.

—C. A. M.

Clupanodonic acid: Occurrence of — in dab and green turtle oils. M. Tsujimoto. J. Coll. Eng., Imp. Univ., Tokyo, 1908, 4, 177–179.

THE dab oil obtained from an unknown species of fish (probably *limnulus*) was a reddish-yellow liquid with a very unpleasant odour. It gave the following values:—Sp. gr. at 15° C., 0.9210; acid value, 0.83; saponification value, 185.32; iodine value (Wijs), 118.53; refractive index (20° C.), 1.4748; m.p. of fatty acids, 29° C.; brominated acids insoluble in ether, 18.66 per cent.; and oxidised acids (Fahrian), 0.72 per cent. Green turtle oil, obtained from *Chelonia midas* Linna., was a pale yellow liquid with a somewhat fishy odour. It gave the following analytical values:—Sp. gr. at 15° C., 0.9335; acid value, 1.27; saponification value, 193.80; iodine value (Wijs), 127.38; refractive index (20° C.), 1.4769; m.p. of fatty acids, 31.5° C.; insoluble brominated acids, 29.45 per cent.; and oxidised acids, 2.51 per cent. The insoluble bromide from the fatty acids of each oil turned black at 200° C., decomposed without melting, and had an elementary composition agreeing with that of clupanodonic octobromide (this J., 1906, 818, 819). The amounts corresponded to a proportion of 5.63 and 8.88 per cent. of clupanodonic acid in the respective mixed fatty acids.

—C. A. M.

Oils and fats, and especially marine animal oils: Cause of the odours of —. M. Tsujimoto. J. Coll. Eng., Imp. Univ., Tokyo, 1908, 4, 181–191.

A NOTION relationship may be observed between the amount of odour of an oil and the degree of unsaturation. The author attributes the disagreeable odour of marine animal oils largely to the presence of glycerides of highly-unsaturated fatty acids, especially those of the series $C_nH_{2n-8}O_2$. Thus, Japanese sardine oil, which contains a large proportion of clupanodonic acid, has a much more pronounced fishy odour than herring, whale, dab, or turtle oils, which contain less of that acid. This was supported by the fact that on treating a solution of the fatty acids from Japanese sardine oil with bromine, filtering off the insoluble octobromide, and reducing the brominated fatty acids in the filtrate, the acids obtained were practically free from the original unpleasant odour, though still possessing an odour. The precipitated octobromide was odourless, but when reduced with alcoholic hydrochloric acid and zinc dust, it yielded clupanodonic acid with the characteristic fishy odour of the oil. Future investigations of the problem of deodorisation of these oils should therefore aim at the complete removal of glycerides of the clupanodonic acid series or of their conversion into non-odorous compounds.—C. A. M.

Marine animal oils: Nature of the resinous substance deposited from the mixed fatty acids of — on keeping. M. Tsujimoto. J. Coll. Eng., Imp. Univ., Tokyo, 1908, 4, 193–195.

THE resinous deposits formed on keeping the fatty acids of Japanese sardine and whale oils were nearly insoluble in petroleum spirit, ether, and carbon tetrachloride, but more soluble in absolute alcohol and readily soluble in caustic alkali solution, yielding a dark brown liquid. When washed with petroleum spirit they were reddish-brown, nearly odourless, friable solids, heavier than water, and decomposing before their melting points were reached. The oils from which they had separated showed a great decrease in their iodine values and in the yields of octobromide. Analyses of the substances dried over sulphuric

acid gave results indicating the formula, $C_{18}H_{28}O_2$, O_4 , and it was concluded that they were oxidation products of chupanodonic acid or other acids of the series $C_nH_{2n-8}O_2$. On passing a current of air through the fatty acids of fresh Japanese sardine oil heated to about $80^\circ C$. for 5 hours daily for 10 days, the acids became turbid and thick, but did not yield a deposit.—C. A. M.

Marine animal oils; Oxidised fatty acids of ——. M. Tsujimoto. J. Coll. Eng., Imp. Univ. Tokyo, 1908, 4, 197—200.

CERTAIN marine animal oils, including Japanese sardine oil and cod-liver oil, yield insoluble compounds when kept, and this is still more marked in the case of their free fatty acids. Old marine animal oils or those bleached by sunlight gave brownish-black soaps on saponification. The effect of insolation (as frequently used in Japan for refining oils) is to render the colour lighter, change the odour, and increase the viscosity. The specific gravity and saponification value are distinctly increased, the acid value and refractive index slightly increased, and the iodine value and yield of octobromide distinctly decreased. The oxidised acids show a great increase (e.g., 2.57 and 2.13 per cent. were obtained after a week's exposure). The liberated oxidised fatty acids were brownish-black, viscous solids, drying to a dark brown film when exposed in a thin layer. After drying at $100^\circ C$. they only dissolved with difficulty in alcohol. They appeared to be mainly oxidation products of acids of the chupanodonic series, though not identical with the resinous substance deposited from the fatty acids on keeping (see preceding abstract). From a technical point of view the dark coloration of the soap yielded by marine animal oils containing as little as 0.27 per cent. of oxidised acids is important, and glycerides of fatty acids of the series $C_nH_{2n-8}O_2$ ought to be removed or converted into indifferent compounds if such oils are to be used in soap-making. The oxidised acids from linseed, perilla, or tung oils do not give such intense colorations on saponification.—C. A. M.

Wool waste saturated with boiled oil; Spontaneous combustion of ——. R. Nowicki. Glückauf, 1909, 45, 222—224.

THE boiled oil used in the author's experiments absorbed 10.33 per cent. of oxygen in 42 hours when exposed to the air in a thin film on glass, the greatest degree of absorption (1.345 per cent.) taking place in the first 2 hours. Weighed quantities of 40 grms. each of wool waste were impregnated with definite amounts of this oil and placed in a flask, the body of which was packed in a box of cotton wool. Air was drawn through the flask by means of an aspirator in such quantity that samples taken from the aspirator still contained 14 to 15 per cent. of oxygen. A thermometer was introduced into the middle of the impregnated material, whilst the pressure was regulated by means of a water manometer. It was found that risk of ignition began when the ratio of waste to boiled oil was as 2 : 1, and that ignition was certain to occur when the ratio was as 1 : 1. Under these conditions spontaneous combustion took place in 79 minutes when the temperature had reached $131^\circ C$. With proportions of 2 : 3 and 1 : 2, ignition did not take place below $180^\circ C$.—C. A. M.

Dust-laying oils. Heise. See XVIII B.

PATENTS.

Oils, fats, waxes, and their products; Impts. in, and apparatus for filtering ——. J. Doull. London. Eng. Pat. 10,277, May 12, 1908.

THE apparatus consists of a circular wrought-iron tank with a roof, and a perforated wooden floor, carried on iron girders and supported on an angle-iron ring. The floor is covered with canvas duck laid on cocoanut matting. There is a space beneath the floor, from which pipes lead away the filtered material, after its passage through the filtering medium. This may consist of fuller's earth, magnesium silicate, etc., and forms a layer about 2 ft. 6 in. thick above the canvas duck. Filtration is assisted by

means of a vacuum pump connected with the space below the floor of the filter. The filtering medium may be cleansed by washing with boiling water or steam, and subsequent calcination. Heat may be applied when necessary.—E. W. L.

Oil; Apparatus for decolouring, bleaching, and thickening ——. J. C. L. van der Lande, Deventer, Holland. Eng. Pat. 17,670, Aug. 22, 1908.

THE oil is heated and mechanically agitated in a circular boiler, whilst meanwhile subjected to the action of compressed air. The passage of this air upwards through the oil is retarded by means of a series of superposed partitions, attached alternately to the shaft of the agitator, and to the inside of the boiler.—C. A. M.

Fat-extraction apparatus. W. Schmücker. Ger. Pat. 205,423, May 22, 1906.

THE apparatus consists of two concentric vessels, communicating below by means of a filter. The material to be extracted is contained in the inner vessel, into which fresh solvent is introduced at the top, the solution of the fat being thus forced out at the bottom, through the filter, into the annular space between the two vessels. The solution is discharged from the annular space by means of a siphon.—A. S.

Fatty acids; Conversion of liquid — into solid fatty acids. P. Sabatier. Fr. Pat. 394,957, Dec. 12, 1907.

LIQUID fatty acids are converted into solid fatty acids by the action of hydrogen, or a gas rich in hydrogen, in the presence of finely divided metals kept at a suitable temperature ($200 - 100^\circ C$). The vapours of the resulting solid fatty acids are carried forward by the rapid current of gas and condensed, the excess of hydrogen being recovered and used again. The unconverted liquid fatty acids in the product are separated by expression and again treated with hydrogen.—C. A. M.

Soaps of every kind; Apparatus and process for making ——. L. Rivière. Second Addition, dated July 27, 1908, to Fr. Pat. 374,179, Jan. 12, 1907. (See this J., 1907, 769, 881.)

THE apparatus described in the original patent may be constructed in the form of an autoclave, so as to effect more rapid saponification at pressures above that of the atmosphere. In the decomposition of insoluble (calcium, barium, magnesium, etc.) soaps, carbonic acid under variable pressures may take the place of mineral acids. In the case of ordinary alkali soaps the process may be accelerated by the injection of ozonised air in place of ordinary air, the material circulating over the perforated diaphragms being thus thoroughly subdivided. Claim is also made for the separation under pressure of the glycerin, by means of superheated steam or otherwise, from the crude product circulating over the diaphragms.—C. A. M.

Soaps; Preparation of solutions of resinous —, with or without the addition of thickening or colouring matters. F. Arledter. Fr. Pat. 395,177, Dec. 19, 1907.

ROXIN soap is heated in a steam-jacketed reservoir until sufficiently fluid to pass into the solution tank. On the way the soap meets a current of hot water coming from a steam injector and carrying with it the thickening and colouring substances, and is mechanically mixed with it in a finely-divided state. Solution is thus rapidly effected without the soap having come into direct contact with steam.—C. A. M.

XIII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, &c.

(A).—PIGMENTS, PAINTS.

Lead chromate; A preliminary study of ——. E. E. Free. J. of Phys. Chem., 1909, 13, 114—137.

AFTER a review of the literature, the author describes experiments on the precipitation of lead chromate under

varying conditions. Although the size of the crystals of the precipitate increases continuously with decrease in the concentration of the solutions, the colour of the precipitate is lighter from the more concentrated and from the more dilute solutions, than from the intermediate solutions. The two most probable causes of the differences in the colour of the precipitates are varying basicity and varying size of crystal. The best conditions for the manufacture of chrome yellow should be attained by use of cold and concentrated solutions, mixed with rapid stirring and with precautions to prevent the formation of basic chromate. (See also this J., 1909, 30.)—A. S.

PATENTS.

Pigments; Process for producing — A. Moffatt, Assignor to Alba Manufacturing Co., Indianapolis, Ind. U.S. Pats. 911,832 and 911,833, Feb. 9, 1909.

(1). A PIGMENT consisting of co-precipitated barium sulphate and zinc oxide is prepared by adding barium chloride and zinc sulphate consecutively to a mixture of water and excess of calcium oxide, in proportions equivalent to the dissolved calcium oxide. The water is then allowed to become saturated once more with calcium oxide, and the operations repeated. (2). The precipitate obtained by the interaction of solutions of calcium oxide and zinc sulphate is treated with barium chloride solution.—C. A. M.

(B.)—RESINS, VARNISHES.

Rosin; Stability of — at slightly elevated temperatures. C. H. Rerty and W. S. Dickson. J. Ind. and Eng. Chem., 1909, 1, 68—69.

SCHWALBE (this J., 1905, 1214) found that American rosin decomposes when heated at 120°—140° C., with liberation of carbon dioxide. The authors find that if freshly-prepared American rosin be freed from traces of spirits of turpentine—which yields carbon dioxide on heating—it can be heated at 140° C. without any formation of carbon dioxide, provided oxygen and moisture be excluded, for instance in a current of dry nitrogen. With a commercial specimen of rosin, on the other hand, carbon dioxide was formed even on heating in dry nitrogen. The resin acids separated from the oleoresin of *Pinus heterophylla* also yielded carbon dioxide when heated in a current of dry nitrogen to just above the melting point.—A. S.

Japanese lacquer; Drying of — at a high temperature. K. Miyama. J. Coll. Eng., Imp. Univ., Tokyo, 1908, 4, 201—204.

A LAYER of urushiol or of the lacquer hardens within 5 hours at 100° C., within 30 minutes at 150° C., and within 10 minutes at 180° C. (see this J., 1908, 456). This method of drying at a high temperature is used in lacquering metal-work, glass, porcelain, papier-maché, etc., and yields a more durable layer than that obtained by the usual method of drying at the ordinary temperature. In practice, the best results are obtained by thinning the lacquer with turpentine oil or other solvent. As the layer turns brown at a high temperature, lacquers of light colour should be dried at 120°—150° C., and even in the case of dark lacquers the temperature ought not to exceed 180° C. Since the lacquer blackens most pigments, only a limited

number of coloured preparations is available. Of white pigments barium sulphate and bismuth oxychloride are used, the former being preferable when the drying is to be done at a high temperature. In any case the final colour is a greyish or yellowish white. Red lacquers are prepared with vermilion and red oxide of iron; blue with Prussian blue; yellow with cadmium sulphide, lead chromate, and orpiment; green, with chromium oxide; and black with lampblack or (to obtain a more brilliant layer) with iron powder or some compound of iron. A golden coating is obtained by lacquering the article with a mixture of 10 parts of finished lacquer, 1 to 3 parts of gamboge, and 5 parts of solvent, and drying it for about 2 hours in an air-oven at 120° C. Several organic lakes may be used in coloured lacquers, but they are decomposed when heated, and do not yield the proper colours when the coating is dried at a high temperature.—C. A. M.

Rubber; Exports of Pará — from Straits Settlements. Board of Trade J., March 11, 1909. [T.R.]

THE Registrar of Imports and Exports at Singapore reports that 3,659,906 lb. of Pará rubber were exported from Singapore and Penang in 1908, as compared with 2,089,777 lb. in 1907. The countries supplying Pará rubber were the Federated Malay States, Johore, Malacca, and Sumatra, and a small quantity was locally grown. The quantities sent to the various destinations are shown in the following statement:—

To—	1907.	1908.
	lb.	lb.
United Kingdom	1,625,583	3,004,833
Continent of Europe	155,296	310,847
United States of America	4,182	400
Ceylon	231,180	310,489
Australia	31,839	21,419
Japan	11,697	11,569
Total	2,089,777	3,659,906

Rubber exports from Pará, Brazil, in 1908. Board of Trade J., March 4, 1909. [T.R.]

THE exports of rubber from the Consular District of Pará in 1908 were as follows:—

	Fine.	Medium.	Coarse.	Caucho.	Total.
	kilos.	kilos.	kilos.	kilos.	kilos.
Pará	8,804,924	1,216,470	5,609,024	2,936,843	17,514,261
Manáos	9,410,375	1,876,325	2,345,556	4,195,792	17,556,048
Iquitos (transit)	454,800	460,532	209,294	734,458	1,859,093
Itacoatiara	80,800	5,639	48,253	22,363	157,055
Total	18,847,938	3,558,966	8,300,127	6,989,456	37,686,487

The total exports of rubber from the Pará district in 1907 amounted to 37,514,152 kilos, and in 1906 to 34,767,755 kilos.

PATENTS.

Rubber; Treatment of —. [Preparation from latex.] L. Norzagaray, London. Eng. Pat. 2787, Feb. 7, 1908.

RUBBER latex, to which formaldehyde or other preservative may be added in order to prevent premature coagulation or putrefaction, is poured into long trays, fitted in an outer case containing hot water. The latex is then coagulated by the addition of a dilute solution of pyroligneous acid, or of a mixture of acetic and carbolic acids. The coagulum forms a soft spongy mass, which is removed from the tray on to the endless canvas band of an apparatus consisting of two corrugated rollers, actuated by a crank or handle. On this band the rubber is carried between the rollers where it is pressed free from superfluous water. It is claimed that the rubber thus obtained is free from impurities, and contains only a certain percentage of water, which may be removed or not before packing.

—E. W. L.

India-rubber; Manufacture of sheet — and coating or facing fabrics with india-rubber. T. Gare, New Brighton. Eng. Pat. 3112, Feb. 12, 1908.

THE invention embodies a development of the process described in Eng. Pat. 12,454 of 1906 (this J., 1907, 539), and has for its object the production of sheet india-rubber, or of rubber-coated fabrics, in one continuous operation, from powdered or plastic materials (waste vulcanised rubber). The materials are fed in between two endless bands, preferably of steel, or between an inner steel band and the fabric to be coated; these bands are kept taut, and pass over two flanged drums, on the first of which the materials are merely subjected to pressure in order to form them into a compact sheet, and remove air from between the particles, whilst the second drum is provided with means whereby the rubber mass may be heated while still under pressure, and thus formed into a solid sheet, which after being cooled can be removed from between the bands and wound on a suitable contrivance.—E. W. L.

Pura rubber; Manufacture of artificial —. J. Blum and A. W. Carpenter. Fr. Pat. 395,027, Oct. 8, 1908.

SEE U.S. Pat. 904,470 of 1908; this J., 1908, 1214. For the preparation of the iron derivative used in the process, the disintegrated roots of plants of the Iris family are extracted with hot water, the solution treated with chlorine to form a hydrochloride of iron, and the latter converted into a nitrogenous compound by the addition of a suitable substance, preferably an amide. The resulting precipitate is separated after the addition of mineral salts, preferably a mixture of sodium bicarbonate and calcium carbonate.

—C. A. M.

Ebonite capable of resisting the action of chlorine; Manufacture of —. M. Wilderman. Fr. Pat. 395,101, Oct. 8, 1908. Under Int. Conv., Aug. 31, 1908.

RUBBER containing as little resin as possible (not more than 4 per cent.) is mixed with sufficient sulphur to form a product of the composition, $C_{10}H_{16}S_2$, and the mixture is vulcanised as far as possible without interfering with its physical properties. The unsaturated bonds of the poly-prene being saturated with sulphur offer much greater resistance to the action of chlorine. An addition of 5 to 15 per cent. of graphite to the mass before vulcanisation causes the final product to be practically unaffected by chlorine.

—C. A. M.

Elastic or plastic products; Manufacture of —. R. W. Wallace and G. Reynaud. Fr. Pats. 395,214 and 395,215, Dec. 20, 1907.

PRODUCTS resembling caoutchouc, etc., are obtained by placing carbohydrates, such as sugar, in a bath of vegetable oil heated above 200° C., and cooling the viscous mass that is immediately formed. The elasticity of the substance is greater in proportion to the temperature of the bath. To effect vulcanisation the products are incorporated with

sulphur while still liquid and at a temperature sufficient to melt the sulphur. The gum-resins extracted from the bark, etc., of trees belonging to the *Xanthorrhoea* family and of other plants yielding similar gum-resins, may be used instead of carbohydrates.—C. A. M.

Caoutchouc; Synthetic production of —. A. Heinemann. Fr. Pat. 394,795, Sept. 30, 1908. Under Int. Conv., Oct. 2, 1907.

SEE Eng. Pat. 21,772 of 1907; this J., 1908, 1075.—T. F. B.

Tanning extract; Testing of —. A. Gansser. Collegium, 1909, 37—41.

THE author points out that there is at present no reliable and sufficiently sensitive method for testing the colour of tanning extracts—an exceedingly important factor in the control of extract manufacture. (See this J., 1909, 101, 211.)

A new method is therefore suggested. If cotton is treated with hide substance or gelatin, an artificial product is obtained, which is coloured by tanning extracts the same tint as hide itself, but is far more constant than the latter and shows greater sensitiveness to small colour differences in an extract. This "animalised cotton" is prepared in the following way:—A cotton of fine texture, 1 mm. in thickness, is cut into strips, 11 cm. wide and 20 m. long, passed through boiling water, pressed, and then wound on a spool. This spool, A (see fig.), is placed in a frame above a jacketed tin vessel, B. On two parallel bars C, C₁, which lie on the inner wall of the

vessel, two rims, D, are fastened, from which three glass tubes, E, are suspended. The vessel is filled with a 1 per cent. formaldehyde solution, and the cotton is drawn from spool, A, under E and wound on to spool, F. The formaldehyde is then removed and replaced by a 6 per cent. solution of gelatin (mark I and K). The cotton is drawn four times through the gelatin solution, which is kept at a temperature of 60–65° C., and is then carried over a revolving copper cylinder, C. A smaller copper cylinder, H, is attached to a lever, HJK. By means of the screw, J, the roller, H, can be brought to bear against the cylinder, G. Between the two cylinders, two small pieces of copper plate are placed, the distance between them being adjusted to exactly 1 mm., so that all superfluous gelatin is removed from the cotton. After cooling, the cotton is laid horizontally on trestles and allowed to dry in a dust-free room. A colour test is carried out in the following manner:—10 c.c. of a tanning extract (25 B.) are dissolved in 20 c.c. of water, giving a liquor of about 6 B. The "animalised cotton" is cut into pieces weighing 2½ grms. each, and two of these are soaked in water at the ordinary temperature, rolled into a cylindrical shape, and placed in the liquor. After standing a short time, the cotton flattens out, and along with the liquor it is transferred to a glass cylinder. This is fixed into a frame revolving 25 times per minute and left to agitate for 12 hours. The completely tanned cotton is thoroughly rinsed in running water for 10 minutes, and then lightly pressed. The material is dried in the same way as leather, gradually increasing the temperature up to 30° C. By pressing the material when dry, a better finish is said to be obtained on the test sample.—S. XV.—MANURES, &c.

Soil acidity in its relation to lack of available phosphates. C. W. Stoddart. J. Ind. and Eng. Chem., 1909, 1, 69–74.

It has been shown previously (Whitson and Stoddart, J. Amer. Chem. Soc., 29, 757) that, in general, acid soils need a phosphate fertiliser. In order to ascertain whether this lack of available phosphate in acid soils is due, at least in part, to the solution of phosphates by the free acid present, with subsequent precipitation as insoluble phosphates of iron and aluminium, samples of twelve soils were treated with: (1), a 1 per cent. solution of sodium hydroxide at 100° C.; and (2), N/5 nitric acid

at 40° C. Control experiments showed that the caustic soda solution dissolved from wavellite (basic aluminium phosphate), 99.4 per cent.; from dufrénite (basic iron phosphate), 90.4; and from apatite (calcium phosphate), 8.1 per cent. of the total phosphoric anhydride. N/5 nitric acid, on the other hand, dissolved 95.4 per cent of the phosphoric anhydride from apatite, 4.4 from dufrénite, and 9.1 per cent. from wavellite. The results of the experiments showed that acid soils contain more of their total phosphoric acid in the form of iron and aluminium salts and less in the form of calcium phosphate than do non-acid soils, and especially show a higher ratio of iron and aluminium phosphates to calcium phosphate than the latter. It is pointed out that N/5 nitric acid forms a good indicator of soil needs with respect to phosphates, owing to its action as a selective solvent for calcium phosphate. In the case of Wisconsin soils, if the percentage of phosphoric acid soluble in N/5 nitric acid is less than 0.015, then the soil will respond to phosphate manuring. It was also observed that as the amount of humus in a soil decreases, the percentage of phosphoric acid in the humus increases, apparently indicating that phosphoric acid in this form is unavailable to plants.—A. S.

PATENT.

Fertiliser: Production of a —. O. F. Carlson. Fr. Pat. 395,197, Oct. 13, 1908. Under Int. Conv., Nov. 9, 1907.

A MIXTURE of crude phosphate with calcium cyanamide, calcium dihydrazide or both, is treated with sulphuric acid, as in the manufacture of superphosphates, with the object of obtaining a fertiliser containing phosphoric acid soluble in water and nitrogen in a form readily assimilated by plants.—C. A. M.

XVI.—SUGAR, STARCH, GUM, &c.

Sugars: Colour reactions of indolic substances with —. J. Guezda. Compt. rend., 1909, 148, 485–487.

TEN c.c. of a concentrated aqueous solution of dextrose are heated to brisk ebullition and treated with 2 drops of caustic soda solution, 6–10 mgrms. of dry α -methylindole then being added at once. After thoroughly distributing the methylindole throughout the liquid, the whole is allowed to stand for 2 minutes, and then cooled rapidly. Two drops of fuming hydrochloric acid (sp. gr. 1.12, acid of this concentration being essential) are now added, and, when the liquid has become light in colour a further quantity of 3 c.c., or slightly more, of the same acid is added. The reaction yields a fine, green precipitate, which, if the operation has been carefully executed, consists of two green substances: if too much hydrochloric acid has been used, the precipitate also contains a resin. Attempts to isolate a body of definite melting point from the precipitate were unsuccessful. The author considers that the reaction should be of value in connection with the chemistry of chlorophyll, and describes the reactions obtained with various sugars, both at the ordinary temperature, and also when the hydrochloric acid is allowed to act on the liquid heated to at least 85° C. The following compounds yield green precipitates from cold solution:—*i*-Xylose, *i*-arabinose, rhamnose, dextrose, mannose, galactose, levulose, "gambiose," maltose, and lactose; under the same conditions, glucosamine (hydrochloride) gives a red precipitate. From the hot solution, rhamnose, dextrose, galactose, levulose, and lactose yield green precipitates, *i*-arabinose, "gambiose" and glucosamine (hydrochloride) yield red precipitates, whilst with *i*-xylose, mannose, and maltose, the colours of the precipitates are Bordeaux red, brown, and violet-grey respectively. Sucrose, raffinose, inositol, and amygdalin do not give precipitates either from cold or hot solution. Whilst in the hot solution, dextrose gives a green precipitate with α -methylindole, azure-blue, and brown precipitates are obtained with N-methylindole and β -methylindole respectively.—L. E.

Methylpentoses and pentoses; Detection of —. L. Rosenthaler. Z. anal. Chem., 1909, 48, 165—172.

SEVERAL methods have been proposed for detecting methylfurfural in the mixture of this substance and furfural obtained by distilling a mixture of methylpentose and pentose with hydrochloric acid. The Maquenne-Tollens method consists in heating the distillate with alcohol and sulphuric acid, a green coloration and absorption band between the green and blue indicating presence of methylfurfural; the same band is obtained by the Widtsch-Tollens method (this J., 1900, 172). It may also be obtained by merely heating the methylpentose with concentrated hydrochloric acid, and 0.44 mgrm. of rhamnose may thus be detected with certainty; in presence of much pentose, the test is less sensitive, but 0.44 mgrm. of rhamnose shows the reaction even in presence of 10 times the quantity of xylose. The following is another method for detecting methylpentoses in presence of pentoses:—The substance is heated for 10 minutes in a boiling water bath with about 10 c.c. of concentrated hydrochloric acid and about 1–2 c.c. of acetone: methylpentoses give a red colour and a band which covers the D-line and extends somewhat to right and left of it. The colouring matter can be extracted with a liquid phenol such as guaicol. By the above method (also applicable to detection of methylfurfural in distillates) 0.15 mgrm. of rhamnose can be detected even in presence of 10 times as much pentose. The latter, on heating with hydrochloric acid and acetone, gives a reddish colour at first, but, in the course of 10 minutes, brown liquids, with no characteristic spectrum, are produced. With prolonged heating, the colour and band characteristic of methylpentoses, gradually disappears. The author also describes another test for pentoses in presence of methylpentoses. The distillate obtained on heating with hydrochloric acid is treated with about an equal quantity of concentrated hydrochloric acid and a few small crystals of resorcinol, and at once examined spectroscopically. If sufficient furfural is present, it is observed that whilst the liquid gradually darkens, a large part of the right half of the spectrum becomes obscured, but an absorption band soon appears in the red, which, increasing in breadth, gradually fills the previously bright space in the centre: with a lower concentration of furfural, this extension may not occur. If the whole spectrum is obscured, a precipitate is gradually thrown out of solution; after the lapse of 10 minutes, the liquid is diluted with water and filtered, the precipitate is washed with water, and dissolved in glacial acetic acid; the filtered solution shows the absorption band between C and D. Pyrogallol acts similarly to resorcinol. The author has applied the above, and other tests, to various natural gums, gum-resins, and glucosides. The resorcinol-, aniline-, and phloroglucinol tests for pentoses all gave positive results in every case. The acetone reaction for methylpentoses was found to be less sensitive than the Maquenne-Tollens reaction, the latter being less sensitive than the Widtsch-Tollens reaction.—L. E.

PATENTS.

Sugar; Process of producing —. M. Altolaguirre and J. Zubillaga. U.S. Pat. 910,037, Jan. 19, 1909.

DRY, low-grade sugar (of about 86° polarisation) is mixed in a receptacle, provided with suitable stirring apparatus, with 4.5–10 per cent. of ordinary sugar syrup containing about 45 per cent. of water. The mixture is transferred to a vacuum pan, and syrup, similar to that before mentioned, is added, or the mixture may be introduced into the pan over a mass of grained or grained and concentrated contents and the syrup then added. As a result of this treatment, the crystals of the low-grade sugar increase in size and a product of high polarisation is obtained.

—L. E.

Sugar juice or similar liquids; Continuous refining and evaporating apparatus for —. F. Tiemann. Ger. Pat. 206,045, Oct. 17, 1907.

In order to remove the impurities which rise to the surface in the evaporation of sugar juice and similar liquids, a special separator is used (see Fig.). It consists of a

chamber, *a*, divided by the annular partition, *b*, into inner and outer compartments. The juice from the evaporator is introduced into the outer compartment by the pipe, *b*, *f*; the impurities rise to the surface, so that only clear juice enters the inner compartment, from which it flows away through the pipe, *c*. The impurities are removed through the pipe, *g*.—A. S.

XVII.—BREWING, WINES, SPIRITS, &c.

Malt extract; The increase in — produced by pre-mashing the malt. W. Windisch. Woch. f. Brau., 1909, 26, 93–97, 109–117.

THE influence of varying the length of time during which the malt lies in cold mash at the ordinary temperature has been investigated. Malts prepared from barley at different stages of growth, from chitting onwards, as well as commercial malts were employed. It was found that at the ordinary temperature the maximum yield of malt extract was obtained in nine hours when properly modified commercial malts were employed, and that the excess of yield obtained above that produced by the standard method of mashing was but small. With under-modified malts, and dried, partly germinated barleys, on the other hand, the yield continued to increase up to the limit of time, fifteen hours, allowed in the experiments, and the excess obtained amounted in the case of the chit-malt to 8 per cent. The influence of the heat at which the mash stood was examined in a commercial malt mashed at various temperatures from 15° C. to 90° C. allowing at each temperature "stands" of three and nine hours. The highest yields, 1.95 and 2.37 per cent. excess, were found with the 3 and 9 hour "stands" at 50° C., the yields increasing with rising temperature to this point and falling away when it was exceeded. The nature of the substances contributing to produce this increase in extract has been studied in several cases and the results show that the extra yield consists chiefly of protein, pentosans, and ash: a part only is due to additional solution of starch and to the solution gravity of the maltose which is produced as a consequence of the pre-mashing. The author regards the pre-mashing method as a continuation of, and partial substitute for, "flooring" in malt, and considers it affords a quick, simple, and economical method of obtaining complete modification of the barley endosperm, thus enabling maximum yields of extract to be obtained from very under-grown malts and reducing the malting time and loss. (See also this J., 1909, 34, 151, 213, 254.)—R. L. S.

Enzymes; Plant —. W. W. Bialosuknia. Z. physiol. Chem., 1909, 58, 487–493.

THE author has examined the seeds of various plants belonging to the Papilionaceae and Gramineae, for pro-

teolytic, oxidising, and amylolytic enzymes. The seeds, which were examined both in the ungerminated state and in various stages of germination, were ground to powder, and then dried *in vacuo* over sulphuric acid until the weight became constant. The experiments were carried out at 37.5° C., and under a-septic conditions.

(1) *Proteolytic enzymes*.—The experiments showed that neither the germinated nor the ungerminated seeds contain an enzyme capable of exerting any proteolytic action on egg-albumin. Fibrin was only digested (as shown by the biuret reaction) in presence of 0.2 per cent. solution of potassium hydroxide. With the exception of rye seeds, all the seeds examined, both ungerminated, and in a state of germination, were found to contain an enzyme capable of coagulating milk. The proteolytic enzymes of the seeds act very vigorously on vegetable proteins; they act on the proteins of oats and wheat both in acid and neutral solutions. Seeds of the *Papilionaceæ* contain stronger proteolytic enzymes than those of the *Graminaceæ*. (2) *Oxidising enzymes*.—Water and 10 per cent. glycerol were used for extracting the enzymes from the ground seeds. The experiments, in which various reagents for oxidising enzymes were used, indicated that different seeds vary in respect of the nature of their oxidising enzymes. Wheat was found to present the strongest reactions. (3) *Amylolytic enzymes*.—One per cent. starch paste was treated with the powdered seed. All the seeds examined were found to possess amylolytic power in varying degrees. The conversion of starch into dextrin (erythro-dextrin) was found to progress fairly rapidly at first, but it was also found that the original blue iodine reaction, which gradually turned to reddish-violet, subsequently reappeared again, finally disappearing after a shorter or longer time. Further experiments indicated that this reappearance of the blue iodine reaction is actually due to reversion of the saccharification, i.e., to a synthesis of starch. In the saccharification of starch with rye seeds, it was found that lactose and dextrose are formed.—L. E.

Fusel oil; Co-operation of bacteria in the formation of—. H. Pringsheim. *Biochem. Zeits.*, 1909, 16, 243–245.

Fusel oil ordinarily consists of *n*-propyl, isobutyl, and amyl alcohols, but the author found also isopropyl and *n*-butyl alcohols in a fusel oil prepared on a large scale from maize (see this J., 1908, 824). These latter alcohols are fermentation products of the ordinary butyric acid bacillus, and hence it was inferred that the fusel oil in question owed its formation to two distinct processes, i.e., (1), the action of yeast on the decomposition products of proteins, and (2), butyric acid fermentation. In support of this view, the author now draws attention to an analysis of fusel oil from potatoes, published by Rabuteau in 1878 (*Compt. rend.*, 1878, 87, 500); in this case also, both *n*-butyl and isopropyl alcohols were present in addition to the ordinary constituents of fusel oil.—A. S.

Benzene and salicylic acids in fermented beverages. Robin. See XXIII.

Disposal of liquid refuse from distilleries. Sixth Report of the Royal Commission on Sewage Disposal. [Cd. 4511.]

COMMENCING with some observations on the production of whisky from malt, the report deals with land treatment by pot ale; the destruction of the refuse by heat; its evaporation followed by torrefaction; purification in contact beds; purification by percolation filters; experiments to ascertain its effect on salmon; purification of refuse from grain distilleries; the attitude of riparian proprietors; and the question of standards.

The conclusions arrived at are:—

(1.) It is practicable to treat the waste liquids from distilleries either on land or on filters to produce a satisfactory effluent.

(2.) For treating these liquids, percolating filters are more efficient than contact beds, and it appears desirable first to dilute the waste liquids and then to treat them with lime before filtering them.

(3.) It is practicable to destroy pot ale by heat. For this purpose the waste heat of the works may be utilised,

but this alone is only sufficient to destroy about one-third of the pot ale produced.

(4.) It is practicable to evaporate pot ale and then to incinerate the syrup so as to produce manure which at present sells fairly well at about £5 per ton. The revenue from the sale of such manure falls far short of the expenditure required to produce it. There is some risk of atmospheric nuisances with these destructor and evaporation processes, as at present carried on, and the distillate from the evaporation process would be liable to cause a nuisance if discharged into a small stream.

(5.) The cost of the various methods of dealing with the waste liquids from distilleries would depend largely on local circumstances. Where suitable land was available at an agricultural price, land treatment would be the most economical process to adopt, but great care would be required to secure that the land is not overdone and that the waste liquids are properly distributed over it.

Of the artificial processes, the plan which has been carried out at Coleburn would be considerably cheaper than any of the destructor or evaporation processes, especially in view of the fact that these processes only deal with pot ale. So that where they are adopted further means must be provided for purifying the other waste liquids. Skilled supervision would be required in all cases, but especially in the case of the process which has been carried out at Coleburn.

(6.) The Central Authority, which the Commissioners recommended to be constituted, should be the final tribunal to determine all questions relating to standards.

(7.) In the case of distilleries situated in towns which are sewered, as a general rule, the liquid refuse should be allowed to enter the sewers. Its admission to the sewers should be subject to regulations and safeguards as recommended in the Third Report dealing with the relations between local authorities and manufacturers in regard to the disposal of manufacturing effluents.

XVIII.—FOODS; SANITATION; WATER PURIFICATION, & DISINFECTANTS.

(A.)—FOODS.

Canned foods; Presence of tin [and determination] in certain—. G. S. Buchanan and S. B. Schryver. Local Government Board Report, No. 7, 1908, 1–130.

THE investigation was carried out for the purpose of ascertaining to what extent canned foods were contaminated with tin, and also the physiological effect of such quantities of tin as were found to be present. One of the authors took daily for one week a quantity of tin salt (the double tartrate of sodium and tin) equivalent to one grain of tin, during a second week two grains daily, and during a third week three grains daily, the doses being administered at meals. There was no evidence of accumulation of tin in the system at the end of the first week, but when two grains were ingested per day, some of the tin appeared to have been absorbed. When the amount taken reached three grains, about two grains were retained in the body during the week. By far the largest amount of the tin taken was excreted with the faeces.

The canned foods examined comprised flesh foods, fish, meat essences and soups, fruits, vegetables, puddings, and jams, the majority of the samples being from five to eight years old. The meat foods, as a class, appeared to have taken up comparatively little tin, the quantity being often less than 0.5 grain per lb.; in only one instance (canned tripe) did it reach 2 grains per lb. A sample of tomato soup contained 3.5 grains of tin per lb., and a sample of lobster 2.39 grains of tin to the lb. The meat extracts examined contained from 0.40 to 5.33 grains of tin per lb., and had absorbed considerably larger quantities of tin than had meats of the same age; it was noticed that large amounts of tin were found when the receptacle contained heads of solder resulting from defective soldering. The largest quantity of tin present in samples of canned pears, peaches, and apricots, which were about 2 years old, was 1.03 grains per lb. It was also

brought out by the investigation that the tin, after solution in the liquid contents of the can, becomes in course of time absorbed in, or chemically combined with, the solid contents (meat, fruit, etc.), so that the latter contain relatively larger quantities than the liquid itself.

From the results of the whole investigation, it is concluded that when food contaminated with tin is eaten, the larger portion of the tin does not become absorbed from the gastro-intestinal tract, and that accumulation of tin in the body under these circumstances takes place at a comparatively slow rate. Whilst it may be concluded that there is not much probability of serious risk of chronic poisoning by the absorption of relatively small quantities of tin as a result of a diet consisting largely of canned foods continued over considerable periods of time, it nevertheless seems clear that in any kind of canned goods, quantities of tin approximating to two grains to the pound are not only unusual but unnecessary, and must be regarded with grave suspicion in consequence of the risk of irritant action of the tin they contain.

It is suggested that sanitary officers, with the co-operation of the public analyst, should pay special attention to canned foods which there is reason to suspect to be of unusual age, e.g., more than one or two years, and, in particular, to such canned goods as are specially liable to act on tin. The presence, in the contents of a sample can, of tin in quantities approaching two grains per lb. may be taken to signify that the food has become potentially dangerous to health, and calls for further examination of other samples with a view to dealing with the consignment in accordance with the results obtained. Some provision for determining the date and place of preparation of canned goods, by means of marks, labels, or otherwise, would be an advantage from several points of view.

For the determination of the tin, 50 grms. of the substance were heated in a round-bottomed Jena flask with 50 grms. of potassium sulphate and 50 c.c. of concentrated sulphuric acid, more of the acid being added, if required to keep the contents of the flask in a fluid condition. When a colourless solution was obtained, it was cooled, diluted with water to about 600 c.c., treated with hydrogen sulphide, and set aside over-night. The mixed precipitate of sulphide, sulphur, and, in some cases, calcium sulphate, was then collected on a filter, washed a few times with water, and the tin contained in it determined as follows:—

Colorimetric process.—The sulphide was dissolved by boiling the precipitate and filter with 5 c.c. of concentrated hydrochloric acid, and the solution filtered into a test-tube, the residue being washed with 2.5 c.c. of concentrated hydrochloric acid. A current of carbon dioxide was next passed into the test-tube and a piece of zinc was added to the hot, acid solution; as soon as the last trace of metal had dissolved, 2 c.c. of the reagent were added, the current of carbon dioxide being continued meanwhile. The reagent was prepared by dissolving 0.2 gm. of dinitrodiphenylaminesulphoxide in 100 c.c. of *N*/10 sodium hydroxide solution, and filtering. After being boiled for a few minutes, the contents of the test-tube were diluted to a volume of 100 c.c., filtered, and the filtrate treated with a drop of dilute ferric chloride solution. The violet coloration produced was then compared with that produced by similarly treating known amounts of tin. This process was found to be useful for sorting purposes and for determining less quantities of tin than 1 grain per lb.; for larger amounts, the gravimetric process was preferred.

Gravimetric process.—The mixed precipitate was dissolved in a small quantity of hot 10 per cent. sodium hydroxide solution, and the sulphide re-precipitated by the addition of glacial acetic acid. The sulphide, thus freed from silica, etc., was then collected on a filter, washed with hot water, dried, oxidised, and weighed as stannic oxide.

—W. P. S.

Vinegar; Determination of mineral acids in — F. Repton. *Monit. Scient.*, 1909, 23, 172—173.

A PORTION of the sample of vinegar is titrated with a solution of calcium succinate, using phenolphthalein as indicator, in order to determine the total acidity. Another portion

of the sample is neutralised with sodium hydroxide free from carbonate, then acidified with phosphoric acid, and submitted to steam distillation until the distillate is free from acidity. The distillate is next titrated with calcium succinate, and, if the acidity thus found corresponds with the total acidity, free mineral acids are in all probability not present in the sample. If there be a difference, sulphuric acid and hydrochloric acid must be determined in separate portions of the sample in the usual way. Nitric acid is not likely to be present. Phosphoric acid is determined by treating a portion of the vinegar with calcium carbonate, evaporating the mixture to dryness, incinerating, and precipitating the nitric acid solution of the ash in the usual manner. The author considers that the process proposed by Richardson and Bowen (this J., 1906, 836) is open to the objection that the incineration converts appreciable quantities of sulphates and chlorides into carbonates, especially in the presence of an excess of an organic acid.—W. P. S.

Proteins; Partial hydrolysis of some — E. Abderhalden. *Z. physiol. Chem.*, 1909, 58, 373—389.

THE author partially hydrolysed edestin from cotton seeds, keratin from wool, elastin, and hæmoglobin by means of 70 per cent. sulphuric acid, and attempted to isolate definite compounds from the reaction products by means of precipitation-reactions with phosphotungstic acid, mercury sulphate, and silver nitrate. From edestin three substances of constant composition were isolated, which on complete hydrolysis yielded respectively: (1), glutamic acid and tryptophan; (2), tryptophan, glutamic acid, and leucine; and (3), tyrosine, glycocoll, and leucine. Attempts are now being made to prepare similar substances synthetically from the components in order to compare their properties with those of the products obtained from edestin. Substances were also obtained, but not in a pure condition, from elastin, hæmoglobin, and keratin of a simpler constitution than the proteins themselves. From the mother-liquor of *D*-alanyl-*L*-leucine from elastin (see Fischer and Abderhalden, this J., 1907, 1165), the author succeeded in isolating *L*-leucyl-*D*-alanine identical with the synthetic product.—A. S.

(B.)—SANITATION; WATER PURIFICATION.

Dust-laying oils for the floors of printing and type-casting establishments; Composition, properties, and application of — R. Heise. *Arbb. Kais. Gesundh.-Amt*, 1909, 30, 93—177. *Chem. Zentr.*, 1909, 1, 699—700.

OF 31 oils examined by the author, 26 were insoluble in water, and 4 were soluble in, or formed emulsions with, water. Of the insoluble oils, 13 consisted wholly of mineral oil; the others contained besides mineral oil, certain quantities (up to 13.5 per cent.) of fatty oils (linseed oil, rape oil, and in one case lanolin), and also in some instances, perfumes, colouring matters, and disinfectants. In one sample, nitrobenzene was detected. A preparation intended for use on linoleum consisted of turpentine oil and paraffin wax; it left behind a solid residue possessing practically no dust-fixing power. The "soluble" oils contained from 46.2 to 82.6 per cent. of mineral oil, rendered soluble or emulsifiable by means of oleic acid soaps, rosin soap, or sulphonated fatty acids. One soluble preparation consisted of an aqueous solution of magnesium chloride and vegetable extractive substances. The author considers that according to present experience the most useful preparations are those consisting entirely of non-

drying oils: mineral oils are most satisfactory. The oil should have a viscosity between 30 and 40 at 20° C. referred to water at 20° C.—A. S.

Nitrites; New reaction for — in drinking water. A. Rochaix. *L'Union pharm.*, 1909, 50, 62—63.

The reagent employed is an aqueous solution of 0.2 gm. of the dyestuff, "neutral red" or "toluylene red" (symmetrical dimethyldiaminotoluphenazine hydrochloride) in 1 litre of water. To 20 c.c. of this reagent, 10 c.c. of the water are added, and 1 to 3 c.c. of 20 per cent. sulphuric acid solution. On agitating, the red to violet colour passes to clear blue in the presence of nitrites. The test is very sensitive; a distinct reaction is given with 0.05 mgrm. of nitrous acid in a litre of water. The sulphuric acid used should be diluted, as indicated, for strong acid would give a blue reaction in the absence of nitrites. Alkaline waters change the initial red tint to yellow, but this does not affect the ultimate appearance of the blue colour due to nitrites.—J. O. B.

PATENTS.

Water; Purifying — by the removal of sulphur [sulphates].

R. Reichling, Königshof-Krefeld, Germany. Eng. Pat. 20,591, Sept. 30, 1908. Under Int. Conv., Oct. 1, 1907.

The removal of sulphates from water is accomplished by the addition of barium carbonate in presence of carbon dioxide, either by allowing water, saturated with the latter, to flow through barium carbonate before adding it to the main body of the water, or by treating the whole of the water with carbon dioxide in presence of barium carbonate, or in other ways. The bicarbonates of calcium and magnesium formed in the process are precipitated by the addition of lime.—E. W. L.

Water; Process for removing sulphur [sulphates] from —. R. Reichling. Fr. Pat. 391,879, Sept. 29, 1908. Under Int. Conv., Oct. 1, 1907.

SEE Eng. Pat. 20,591 of 1908; preceding.—T. F. B.

(C).—DISINFECTANTS.

Disinfecting power of a mixture of spirits of turpentine, phenol, naphthalene, and ether. ("Essence of turpentine d'Oukraina"). E. S. Gribinouk. *Arch. sci. biol.*, St. Pétersb., 13, 470—482. Chem. Abs., 1909, 3, 453—454.

The mixture, used by the author in medical practice, consists of crystallised phenol (2 grms.), crude naphthalene (5 grms.), ether (25 grms.), spirits of turpentine (100 grms.). The naphthalene is dissolved in the ether, the phenol added, and after a complete solution of these, the turpentine is added. The bactericidal action of the mixture is greater than any of its constituents. The following organisms were killed by it, and in the following order:—*Cholera vibrio*, *B. typhi*, and *Staphylococcus albus*. Emulsions of 1:4.2—100 were used. Greater dilutions (1:500—1000), form better emulsions.

Emulsification. Marshall. See XXIV.

XIX.—PAPER, PASTEBOARD, &c.

Paper-making materials and their conservation. F. P. Veitch. U.S. Dept. Agric., Circular No. 41, Dec., 1908.

In the United States the exhaustion of the readily available supplies of pulp wood is within measurable distance. In 1907, 3,962,660 cords of wood were used, yielding 2,547,879 tons of pulp. Economies of the present supplies of wood and the development of other fibrous materials must therefore be considered. As a rule the cost of chemicals and the time of digestion are higher in the case of wood pulp than in the case of other fibres. On the other hand, wood is cleaner, can be dealt with in larger charges, and requires less beating than most other fibres. Good papers of medium grade can probably now be manufactured more cheaply from wood than from other fibres, so that the first cost of any "new" fibre, delivered at

the mill, must be correspondingly lower than that of raw wood. But besides the cost of the raw fibre and the cost of its treatment, the yield of paper obtained must be included in the calculation, and when all these factors are considered, such materials as cereal straws, maize stalks, bagasse, and cotton stalks must, except under special circumstances or for special purposes, remain in the background until cheaper sources are exhausted. Among such special circumstances, there would be included exceptional facilities for collection and transport of the materials to a centre where they could be worked economically. The author proceeds to indicate the materials which should, in his opinion, be developed immediately for relieving the threatened shortage of pulp wood. In the first place comes the "lumber waste," i.e., the trees and portions of trees too small for constructional purposes which are at present left in the forest in the felling of timber wood. Such wastes are estimated to be capable of yielding annually 12,000,000 cords of wood suitable for pulping. This would probably constitute the cheapest source of "new" paper-making material. Next, in a relatively small area of the Northern Central States, about 3,000,000 acres are under cultivation for flax, and at the rate of 1 ton of flax straw per acre, with a yield of 400 lb. of fibre per ton of straw, material for 480,000 tons of strong wrapping or even perhaps white papers should be readily collected. Again, if the "scutching waste" produced from the jute, manila, and sisal fibres imported into the United States could be collected and utilised, material for a further 120,000 tons of strong paper should be available. The total production of vegetable textiles (including ropes, etc.), in the United States is estimated to be 2,030,000 tons per annum. The waste textiles consumed by the paper mills amount to only 400,000 tons, of which 200,000 are imported. Of the balance of 1,800,000 tons, at least 1,000,000 tons should be capable of collection if only the importance of their conservation could be impressed on the people. Again, the annual production of paper in the States is 3,000,000 tons, of which 80 per cent. becomes waste in 3 or 4 years. But the paper mills of the country recover only 580,000 tons of waste paper annually for re-making. Here also there should be at least another 1,000,000 tons of raw material readily available. Only when these immediate and obvious sources fail, can the more costly "new" fibres come into prominence. When these supplies are no longer adequate, it may be necessary to cultivate certain quick-growing materials primarily for paper-making. Finally the author expresses the opinion that paper itself might be economised; that, on the whole, paper-makers fail to develop the full qualities of the fibres they consume. Most papers could be made from 10 to 20 per cent. lighter than they are without using better materials, and 2,250,000 tons of paper of better quality and lighter weight might be made to do the same service now performed by 3,000,000 tons.

—J. F. B.

Sulphite pulp; Determination of resin in —. E. Opfermann. *Z. angew. Chem.*, 1909, 22, 436.

For the estimation of resin in sulphite pulp the method used by the Königl. Materialprüfungsamt in Grosslichterfelde, which consists in extracting 20 grms. of air-dried material with ether in a Soxhlet apparatus for 5 hours and drying the residue at 98°—100° C. until constant in weight, should be adhered to, as if alcohol is used instead of ether, a considerably higher result is obtained.

—J. C. C.

Soda ash [from cellulose digestion]; Causticising of recovered —. W. Schacht. *Papier-Zeit.*, 1909, 34, 351—353.

The complications of the causticising process, when applied to the soda ash recovered from the digestion liquors in the manufacture of cellulose, are well known; they relate chiefly to the concentration of the solution treated and the presence of impurities, particularly the silicates and sulphur salts. The constitution of the precipitate formed (the so-called "lime-mud") is of primary importance as affecting the economy of the process. Denser

precipitates are obtained by the use of pure soft waters than with very hard waters, or waters containing humus matters. Very pure "fat" limes give a higher degree of causticity than "lean" limes, but the latter are more economical because they give a denser precipitate, from which the sodium salts are more readily washed out. It is of the highest importance to determine and employ that ratio between lime and sodium salts which gives the highest efficiency. The lime should be used in lump form and introduced into the soda solution after the latter has been heated to 80°—85° C. The temperature should be maintained at this point, since at lower temperatures the reaction is incomplete and at higher temperatures changes take place in the silicates which adversely influence the clarification of the lye. Strontium oxide gives a far more efficient causticisation than lime, but alone it is too costly. When used in the theoretical proportions, strontium oxide not only effects a far greater conversion of the carbonate than lime does in equivalent proportions, but it also causticises a larger portion of the silicates, as well as about three-fourths of the sulphate which is quite unattacked by lime. In spite of the higher cost of strontium oxide, a real economy can often be effected by performing the causticising operation in two stages, doing the bulk of the work with lime, decanting the liquor and adding to it the calculated quantity of strontium oxide necessary for the conversion of the residual non-caustic sodium salts.—J. F. B.

Cellulose hydrates. H. Ost and F. Westhoff. *Chem.-Zeit.*, 1909, 33, 197—198.

Cross and Bevan have applied the name of "hydrates" to those modifications of cellulose containing, in addition to hygroscopic moisture, which is dependent on atmospheric conditions, "water of hydration" which is dependent on their constitutional modification and is more firmly held than ordinary hygroscopic moisture. Thus they have indicated for mercerised cotton the formula $(C_6H_{10}O_5)_2 \cdot H_2O$, and for the cellulose regenerated from viscose the formula $(C_6H_{10}O_5)_n \cdot H_2O$. In the case of the hydrocelluloses, on the other hand, the cellulose has permanently entered into chemical combination with water to form new derivatives, and such products can be termed "hydrates" only in the same sense as the dextrins, maltose, etc., might be termed "hydrates of starch." Schwalbe (this J., 1907, 1291) has endeavoured to distinguish between hygroscopic moisture and water of hydration by assuming that the former is entirely expelled at 100° C., whilst the latter is only driven off at the temperature of boiling toluene; but such a distinction has been found to be invalid. The exact determination of hygroscopic moisture in members of the cellulose and starch groups is a very difficult problem. Small progressive losses of weight are recorded as the temperature of drying is increased from 100° to 130° C., no absolutely fixed point being reached in any case. A number of determinations carried out by the authors have led them to conclude that, at a temperature of 125° C., the true hygroscopic moisture may be determined with an error of ± 0.1 per cent. The best results are obtained by slowly increasing the temperature up to a maximum of 125° C., in a current of dry hydrogen or carbon dioxide. But under whatever conditions the desiccation be effected, it is universally recognised that the hydrated celluloses (mercerised cotton, viscose-cellulose, etc.) contain considerably more, and the hydrocelluloses rather less hygroscopic moisture than normal cotton cellulose. The authors, however, do not recognise the existence of "water of hydration," as distinct from hygroscopic moisture, as a constitutional component of these modified celluloses. They have proved by a large number of elementary analyses that, after the hygroscopic moisture has been expelled by drying at a temperature of 120°—125° C., mercerised cotton and the cellulose regenerated from viscose both possess the same empirical formula, $(C_6H_{10}O_5)_n$, as normal cotton cellulose. This applies only when the cellulose is regenerated from the viscose after a short time. In the case of "aged" or ripened viscose, the cellulose undergoes gradually a true hydrolytic change under the continued action of the alkali, with the result that, after 3—4 weeks, the regener-

ated cellulose no longer possesses the normal composition, but contains more hydrogen and less carbon, as in the case of the hydrocelluloses, to which group these degraded products presumably belong. It is noted that starch also undergoes hydrolysis under the prolonged action of alkalis, yielding an analogous series of products.—J. F. B.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENTIAL OILS, & EXTRACTS.

Senecio latifolius; The alkaloids of —. H. E. Watt. *Chem. Soc. Proc.*, 1909, 26, 68.

THE author has made a chemical examination of *Senecio latifolius* (N.O. *Compositæ*), a poisonous plant which grows in South Africa, collected before flowering and also after flowering, and has isolated two new alkaloids of the formulae, $C_{16}H_{27}O_8N$ and $C_{18}H_{35}O_7N$, respectively, for which the names *senecifoline* and *senecifolidine* are proposed. The proportion of these substances present in the plant before flowering is equivalent to 1.20 per cent., whilst in the mature plant it only amounts to 0.49 per cent. *Senecifoline* crystallises in colourless, rhombic plates, which melt at 194—195°, and has $[\alpha]_D = +28^\circ 8'$; it forms well-defined salts with nitric, hydrochloric, or hydriodic acids, and also an *aureichloride*. It can be decomposed by alkali into a hitherto undescribed dicarboxylic acid, $C_{10}H_{16}O_6$, which it is proposed to name *senecifolic acid*, and a new base, $C_8H_{11}O_2N$, for which the name *senecifolinine* is suggested. *Senecifolidine* crystallises in colourless, rhombic plates, which melt at 212°, and has $[\alpha]_D = -13^\circ 56'$; it differs considerably from *senecifoline* in other physical respects, and forms salts corresponding with those mentioned above.

Canadian hemp; The constituents of —. Part II. Cynotoxin. (Preliminary note.) H. Finckmore. *Chem. Soc. Proc.*, 1909, 26, 77.

THE aqueous solution of the alcoholic extract of the root of commercial *Apocynum cannabinum* (this J., 1908, 829) yields on extraction with chloroform, after removing the apocynin with ether (*loc. cit.*), a relatively small quantity of an intensely active substance (cynotoxin), which produces symptoms identical with those caused by the drug itself. *Cynotoxin*, $C_{20}H_{32}O_6$, is a well-defined, colourless substance, which crystallises in small, apparently rhombic pyramids, and melts and decomposes at about 165°. It is sparingly soluble in water and the usual organic solvents, and extremely bitter in taste. Pharmacological investigation by P. P. Laidlaw, has shown that it is an extremely potent drug of the digitalis class and that the pharmacological properties of apocynin (acetovanillone, *loc. cit.*) are negligible. The chemical and pharmacological properties of cynotoxin are still under investigation; it is already evident, however, that it is a dilactone, either of Kiliani's digitic acid, $C_{20}H_{32}O_8$ (this J., 1891, 567), or of a closely related isomeride.

Quinine and its associated alkaloids; Some notes on —. E. Goldsmith. *J. Franklin Inst.*, 1909, 167, 90—98.

A BRIEF account, chiefly historical, of the manufacture of quinine and associated alkaloids.—A. S.

Quinine; Determination of — in quinine tannate and ferrocitrate. E. Rupp and W. Calliess. *Apoth.-Zeit.*, 1909, 24, 159.

1.2 GRMS. of quinine ferrocitrate are warmed with 5 grms. of water; when cold, 5 grms. of sodium hydroxide solution of sp. gr. 1.165 are added and exactly 31 grms. of ether (sp. gr. 0.720); the containing flask is well corked and the contents thoroughly agitated for a few minutes; 0.5 grm.

of powdered gum tragacanth is then added, and agitation repeated, as before. The mixture is then set aside for 5 minutes to clarify, after which exactly 25.1 grms. of the clear ether solution are decanted into a tared capsule. After evaporating the ether, the residue is dried on the water-bath till of constant weight. It represents the amount of quinine in 1 gm. of the ferro-citrate. For quinine tannate the general process is the same as above, but 10 grms. of potassium carbonate solution of sp. gr. 1.330 are used to liberate the alkaloid; 30 grms. of ether are taken and 25.3 grms. of the ethereal quinine solution are decanted for evaporation. The residue, from 1 gm. of the original tannate, should not weigh less than 0.3 gm.

—J. O. B.

Nicotine silicotungstate and determination of nicotine. G. Bertrand and M. Javillier. *Bull. Soc. Chim.*, 1909, 5, 241—248.

The authors have obtained good results with silicotungstic acid as a reagent for the detection and determination of nicotine (see this J., 1899, 404). When dried at 30° C., nicotine silicotungstate has the composition, $12\text{W}(\text{O}_3)_2\text{Si}_2\text{O}_7 \cdot 2\text{H}_2\text{O} \cdot 2\text{C}_{10}\text{H}_{11}\text{N}_3 + 5\text{H}_2\text{O}$; it can be completely dehydrated by heating for 1 hour at 120° C. With a solution containing 1 part of nicotine in 300,000 and 0.1 per cent. of hydrochloric acid, a 5 per cent. solution of potassium silicotungstate produces an immediate turbidity; whilst in solutions containing 1 part of alkaloid per million and up to 8 per cent. of hydrochloric acid, a crystalline precipitate is produced after standing for one or more days. For the determination of nicotine in tobacco, 12 grms. of the sample are boiled for 30 minutes with 300 c.c. of 0.5 per cent. hydrochloric acid under a reflux condenser; the solution is then cooled, the insoluble matter removed in a centrifugal machine or by filtering, and 250 c.c. of the clear liquid treated with a 10–20 per cent. solution of potassium silicotungstate. The precipitate is collected, after 24 hours if the quantity of alkaloid be small, and washed with water to which has been added a little hydrochloric acid and a few drops of the precipitant. It is then mixed with calcined magnesia, and the liberated alkaloid removed by distilling with steam. In the distillate the nicotine is determined by titration with sulphuric acid.

—A. S.

Colechicum corn? Simple methods for the assay of —. A. B. Lyons. *Amer. Drugg.*, 1909, 54, 65.

TWENTY-FIVE GRMS. of colechicum corn, in moderately fine powder, are digested at 50° C. for 6 hours with 80 c.c. of distilled water and 15 c.c. of basic lead acetate solution. The mixture is then transferred to a funnel or percolator, and percolated so that about 2 c.c. pass per minute. When drained, more warm water is added in 20 c.c. portions, until 250 c.c. of percolate have been collected. Five grms. of powdered sodium phosphate are then added, and the precipitated lead phosphate is filtered off. 100 c.c. of the clear filtrate (= 10 grms. of drug) are shaken out successively with 25, 20, and 15 c.c. of chloroform, or enough to extract all the colechicine. The solvent is evaporated off, the residue being evaporated repeatedly with a little alcohol to carry off the last traces of chloroform, and then dried below 100° C. till of constant weight. An alternative volumetric method is that of Heikel (see this J., 1909, 106).—J. O. B.

Rhamnus cathartica, L. [*buckthorn*]; *Chemical examination of the berries of* —. N. Krassowski. *J. Russ. Phys.-Chem. Ges.*, 1908, 40, 1510–1569. *Chem. Zentr.*, 1909, 1, 772–774.

FOUR different methods were used:—(A). The aqueous extract of the berries was shaken with ether, the ethereal solution was evaporated, and the residue extracted with petroleum spirit. The matter insoluble in petroleum spirit was dissolved in alcohol. *Rhamnoxanthin* separated from the solution, and from the mother-liquor, after evaporation with hot toluene, *emodin* and *quercetin* were isolated; *rhamnnetin* was obtained from the residue. (B). The portion of the berries insoluble in water was extracted with ether; from the solution, an oil, *quercetin*, and a resin were obtained. (C). The berries were extracted

first with ether and then with 85 per cent. alcohol; from the solution *rhamnonigrin*, *glucosides*, *xanthorhamnin*, and several *sugars* were separated. (D). Ether extracted from the fruit, *shusterin*, *rhamnocathartin*, and *emodin-anthranol*, besides other substances. The characters of the substances isolated were as follows:—*Quercetin*, $\text{C}_{15}\text{H}_{10}\text{O}_7 \cdot 2\text{H}_2\text{O}$, small needles, m. pt. above 300° C.; *rhamnnetin*, $\text{C}_{15}\text{H}_8\text{O}_7 \cdot \text{CH}_3$, small, light yellow needles, m. pt. above 300° C.; *xanthorhamnin*, $\text{C}_{24}\text{H}_{42}\text{O}_{20} \cdot 7\text{H}_2\text{O}$, needles, m. pt. 220–221° C., yields on hydrolysis, 2 mols. of rhamnose and 1 mol. of galactose. *Emodin*, $\text{C}_{15}\text{H}_{10}\text{O}_5 \cdot \text{H}_2\text{O}$, orange-red needles, m. pt. 254°–255° C.; *rhamnoxanthin*, $\text{C}_{25}\text{H}_{20}\text{O}_9 \cdot \text{H}_2\text{O}$, m. pt. 243° C., yields on hydrolysis, *emodin* and a methylpentose. *Shusterin*, $\text{C}_{25}\text{H}_{30}\text{O}_{13} \cdot \frac{1}{2}\text{H}_2\text{O}$ (?), long, light yellow needles, m. pt. 229°–231° C., is probably a glucoside of *emodinanthranol*. *Rhamnocathartin*, $\text{C}_{27}\text{H}_{30}\text{O}_{14} \cdot \frac{1}{2}\text{H}_2\text{O}$, yellow plates, m. pt. 236° C., appears to be a glucoside of *emodin* and two mols. of a sugar. *Emodinanthranol*, $\text{C}_{15}\text{H}_{12}\text{O}_4$, colourless crystals, m. pt. 280° C., yields *emodin* on oxidation in alkaline solution. *Rhamnonigrin* is a black amorphous mass, yielding methylanthracene on reduction with zinc dust; it is probably a decomposition product of glucosides of *emodin*. The sugars isolated were dextrose, galactose, an unknown pentose, and rhamnose, the three last-named being present in the form of glucosides.—A. S.

Essential oils; Constituents of —. *Eksantalol. Enolisation of aldehydes.* F. W. Semmler. *Ber.*, 1909, 42, 584–591.

EKSANTALOL (this J., 1908, 589) was boiled with acetic anhydride, when tricyclic *enol-eksantalol* monoacetate, $\text{C}_{15}\text{H}_{14}\text{O}_2$, was produced. The pure product boils at 132°–135° C. at 10 mm., has the sp. gr. 1.023 at 20° C., and $n_D = 1.4881$. It has the optical rotation, $\alpha_D = -7^\circ 15'$ in a 100 mm. tube. On heating with dilute inorganic acids to 110° C., eksantalol was produced. Reduction with sodium and alcohol led to the formation of eksantalol, $\text{C}_{11}\text{H}_{14}\text{O}$. When the monoacetate was oxidised with ozone, tricyclic *nor-eksantalone*, $\text{C}_{10}\text{H}_{14}\text{O}$, was obtained, which boils at 101°–102° C. at 10 mm., and gives a semicarbazone melting at 216° C. When reduced with sodium and alcohol, the ketone gave *nor-eksantalol*, $\text{C}_{10}\text{H}_{14}\text{O}$, which boils at 116°–118° C. at 10 mm. *enol-Phenylacetaldehyde* monoacetate, $\text{C}_6\text{H}_5\text{CH}:\text{CH}:\text{O}:\text{C}(\text{OCH}_3)_2$, was produced by the interaction of phenylacetaldehyde and acetic anhydride. This substance boils at 119°–121° C. at 10 mm., has the sp. gr. 1.065 at 20° C., and $n_D = 1.5483$. On oxidation with ozone it yields benzoic acid and benzaldehyde, and on reduction, phenylethyl alcohol. On hydrolysis, it forms phenylacetaldehyde and acetic acid.

—F. SHDN.

Rose oil industry; New departures in connection with the —. G. Marpmann. *Z. Riech- u. Geschmackstoffe*, 1909, 1, 14–15.

LARGE quantities of rose-leaves have been allowed to spoil in Bulgaria owing to the fact that the stills are unable to cope with the leaves as rapidly as they are brought in during the season. Hence better distillation apparatus is needed. The rose-leaves should be collected before sunrise and laid in water. If more are collected than can be dealt with by the stills, they can be preserved by packing tightly in barrels with salt, 3 parts by weight of roses to 1 part of salt. On a larger scale, benzene or ether may be used to extract the oil. The author suggests the use of paraffin hydrocarbons, such as heptane, or a mixture of octadecane and heptane, for the extraction of rose oil.—F. SHDN.

Clove oil sesquiterpenes; A new constituent of —. E. Deussen and A. Loesche. *Z. Riech- u. Geschmackstoffe*, 1909, 1, 15.

IF the fraction of clove oil containing the sesquiterpenes be freed from eugenol and distilled slowly in a vacuum, a solid remains behind. This can be purified by dissolving in chloroform and precipitating by alcohol, and then has the appearance of a white amorphous powder. It gives no coloration with sulphuric acid and glacial acetic

acids. It melts at 146° C., and has the composition, $(C_{11}H_{30}O)_5$. It is present to the extent of about 0.1 per cent. in clove oil.—F. SHDN.

Pyrazine derivatives; New synthesis of — by the interaction of aromatic ortho-hydroxynitroso compounds and acetaldehyde in the presence of ammonia or primary amines. M. Lange. Ber., 1909, 42, 574—577. (See this J., 1908, 471.)

Two pyrazine derivatives have been prepared by the author. α -Nitroso- β -naphthol was suspended in water and dissolved by the addition of sodium carbonate. Commercial acetaldehyde and ammonium chloride were added, the mixture stirred for a time, and warmed. The substance, hydroxydihydronaphthopyrazine, which separated, was purified by dissolving in sodium hydroxide solution and precipitating by adding excess of alkali. On treating the sodium compound in solution with acetic acid, the naphthopyrazine, $C_{12}H_{10}N_2O$, separated in fine needles or minute prisms, which melted at 240° C. By using methylamine hydrochloride in place of ammonium chloride in the above reaction, methylketodihydronaphthopyrazine, $C_{13}H_{12}N_2O$, is produced. This substance, which is used in medicine, crystallises from water or dilute alcohol in colourless needles, which melt at 155.5° C., and dissolve in excess of mineral acids.—F. SHDN.

Hydrocyanic acid; Buignet's method for determining — [with cupric sulphate]; correction and modification. G. Guerin and L. Gouet. J. Pharm. Chim., 1909, 29, 234—236.

BUGNET'S method for the determination of hydrocyanic acid by titration with copper sulphate in presence of ammonia, has been long abandoned, owing to the difficulty of judging the final point of the titration. By the addition of sodium sulphite to the titration liquid, this difficulty is said to be overcome, and the process then becomes accurate and convenient. The standard solution is prepared by dissolving 30.81 grms. of copper sulphate in sufficient distilled water to make 1 litre; each 0.1 c.c. of this is equivalent to 1 mgrm. of hydrocyanic acid. The determination of hydrocyanic acid in cherry-laurel water is performed thus:—25 c.c. of cherry-laurel water, diluted with 75 c.c. of distilled water, are treated with 20 drops of sodium hydroxide solution (sp. gr. 1.332), and 10 c.c. of ammonia solution. In this mixture 0.5 grm. of pure, dry sodium sulphite is dissolved, and the solution is titrated with the standard copper solution until a permanent pale blue tint is evident when the liquid is observed against a white surface. Dilute hydrocyanic acid is similarly determined, but without the addition of sodium hydroxide, which is only used with cherry-laurel water to prevent the formation of hydrobenzamide. The reaction which takes place is represented by the equation: $CuSO_4 + 3NH_4CN = (NH_4)_2SO_4 + Cu(CN)_2 \cdot NH_4CN$.

—J. O. B.

Methyl salicylate. II. Solubility in water at 30° C. H. D. Gibbs. Philippine J. Science, 1908, 3, 357—359. (See this J., 1908, 1175.)

THE solubility of methyl salicylate in pure water at 30° C. is 0.074 grm. per 100 c.c.; in $N/10$ sulphuric acid at 30° C. it is 0.077 grm. per 100 c.c.—F. SHDN.

Chlorophenols; Identification of —. G. Denigès. Bull. Soc. Pharm. Bord., 1908, 328. Pharm. J., 1909, 82, 272.

FOR the identification and differentiation of the chlorophenols used for medicinal or dental purposes, the author makes use of their reactions with formaldehyde. 0.1 c.c. of a 10 per cent. alcoholic solution of the sample is mixed with 2 c.c. of sulphuric acid of sp. gr. 1.84, and then 2 drops of commercial formaldehyde solution are added from a burette made to deliver 40 drops per c.c. The whole is then shaken and the coloration observed. *p*-Chlorophenol gives a more or less greenish brown colour. *o*-Chlorophenol and phenol give an intense carmine; on adding 10 c.c. of

alcohol and shaking, the former gives a turbid, and the latter a clear yellowish-brown colour. If the test be carried out with 1 c.c. of water and 1 c.c. of sulphuric acid of sp. gr. 1.84, instead of with 2 c.c. of the acid, a turbidity or white precipitate is produced. In the case of *p*-chlorophenol this does not change on standing; in presence of *o*-chlorophenol it rapidly becomes feebly rose-coloured, and in the case of phenol, strongly rose-coloured. On now adding 2 c.c. of 90.95 per cent. alcohol and shaking, *p*-chlorophenol gives a clear solution, whilst in the case of *o*-chlorophenol and phenol, the mixture remains turbid. After addition of a further 5 c.c. of alcohol, and shaking, *o*-chlorophenol gives a clear solution, and phenol yields a persistent flocculent precipitate.

Phenol; The compounds which cause the red colour in —. H. D. Gibbs. Philippine J. Science, 1908, 3, 361—370.

IT has been shown that pure phenol is coloured red in the presence of moisture, oxygen, and light, or by oxidation with hydrogen peroxide. The author shows that the principal oxidation products are quinone and catechol, and the red colour of phenol is due chiefly to the presence of quinone or quinone derivatives in solution. The presence of the brilliant red condensation product, phenoguinone, is highly probable.—F. SHDN.

Alcohols; Oxidation of — by the simultaneous action of iron tannate and hydrogen peroxide. E. de Stoecklin. Compt. rend., 1909, 148, 424—426.

CONTINUING his researches (this J., 1909, 111) the author finds that methyl alcohol, and the normal three- and four-carbon homologues are oxidised by iron tannate and hydrogen peroxide, as are also many polyhydric alcohols (glycol, glycerol, sorbitol). *iso*-Propyl, *iso*-butyl, and the higher alcohols of the ethylic series are not attacked. The formation of aldehyde is not the only action which occurs; some of the aldehyde is oxidised to acetic acid, some is absorbed by the tannate, and, in presence of excess of hydrogen peroxide, some is probably transformed into aldehyde-peroxide. In the case of ethyl alcohol, the amount of aldehyde formed increases with the amount of iron present, though not regularly; the increase in the acetic acid is much more regular. When aldehyde is added at the beginning of the experiment, it is oxidised to acetic acid simultaneously with the formation of more aldehyde from the alcohol; this formation of acetic acid only occurs when iron tannate and hydrogen peroxide are both present. If one or other be present alone, a certain amount of aldehyde disappears which is not converted into acetic acid.—J. T. D.

Radioactive emanations [from thorium]; Absorption of — by charcoal. R. W. Boyle. Phil. Mag., 1909, 17, 374—389.

THE percentage absorption of thorium emanation, when mixed with air and led through a vessel filled with charcoal, is found to depend: (1), on the nature of the charcoal, being, for the same sized grains, least for wood, intermediate for animal, and greatest for coconut charcoal, especially for the softer and less dense and gritty kinds of the last; (2), on the velocity of the gas current, being decreased by increasing that velocity; (3), on the extent of the charcoal absorbing surface, increasing as this increases, that is, with the fineness of grain; and (4), on the temperature, following the law for ordinary gases, viz., that a lowering of the temperature of the charcoal causes an increase in the amount of absorption.—F. SHDN.

PATENTS.

Phenacetin. *Process of treating — and product therefrom*. A. G. Meyer, San Francisco, Cal. U.S. Pat. 912,869, Feb. 16, 1909.

A PRODUCT consisting of a mixture of *o*-nitrophenacetin, cresote, and nitro-derivatives of cresote is obtained by mixing phenacetin with a suitable proportion of nitric acid to form a hardened mass, powdering this, mixing it with a suitable proportion of cresote, boiling the whole with water and, after separating from the water, drying and pulverising the residue.—T. F. B.

Phenylarsenious oxide and arsenobenzene. *Process for preparing derivatives of —*. Farbwerke vorm. Meister, Lucius, and Brüning. Ger. Pat. 206,657, April 9, 1907.

By the reduction of *p*-aminophenylarsinic acid and its derivatives, with the exception of the dialkyl derivatives, compounds of the general types, $R_2As:O$, $R_2As:AsR$, and $R_2As(OH)As(OH)R$, are obtained, according to the reducing agent employed. The products destroy trypanosomes in more dilute solutions than atoxyl.—T. F. B.

m-Aminophenylarsinic acid (*Mehrsanilic acid*). *Process for preparing —*. Farbwerke vorm. Meister, Lucius, and Brüning. Ger. Pat. 206,344, Dec. 1, 1907.

m-AMINOPHENYLARSINIC acid is obtained by reduction of the nitrophenylarsinic acid resulting from the nitration of phenylarsinic acid; the reduction may be performed by sodium amalgam in alcoholic solution, or the nitro compound is treated with ammonium sulphide and the sulphur removed by treatment with metallic oxides in alkaline solution.—T. F. B.

Arsenophenols; *Process for preparing —*. Farbwerke vorm. Meister, Lucius, and Brüning. Ger. Pat. 206,456, Dec. 6, 1907.

ARSENOPHENOL and its homologues and derivatives are obtained by reduction of the corresponding hydroxyarylarsonic acids by means of tin and hydrochloric acid, stannous chloride, sodium hydrosulphite, etc. If, instead of these reducing agents, hydriodic acid is used, hydroxyarylarsonic oxides are obtained; these are readily reduced to the arsenophenols by means of sodium amalgam. The hydroxyarylarsonic acids may be obtained by decomposition of diazotised aminoarylarsonic acids. The arsenophenols are more toxic in their action towards trypanosomes than are the hydroxyarylarsonic acids. (Compare Ger. Pat. 206,057; preceding.) T. F. B.

4-Imino-5-isonitrosopyrimidin derivatives; *Process for preparing —*. Farbentfabr. vorm. F. Bayer und Co. Ger. Pat. 206,453, July 26, 1907.

ISONITROSOCYANOACETIC esters, obtained by the action of nitrous acid on cyanoacetic esters, are condensed, in presence of alkaline condensing agents, with urea or its derivatives or substitution products, such as thiourea, guanidine, dicyanodiamide, allophanic esters, etc.; the products are 4-imino-5-isonitrosopyrimidines of the general formula,

where R is hydrogen, alkyl, or aryl, and X represents O, NH, S, CN, etc.—T. F. B.

1-Aryl-2,4-dialkyl-3-halogenomethyl-5-pyrazolones; *Process for preparing —*. Farbwerke vorm. Meister, Lucius, and Brüning. Ger. Pat. 206,637, Oct. 3, 1907.

By the action of halogens on 1-aryl-2,4-dialkyl-3-methyl-5-pyrazolones, addition products are obtained; by removing the elements of hydrohalogen acid from these, monohalogen derivatives are obtained, the halogen being attached to the 3-methyl group.—T. F. B.

1-Methyl-2-nitro-4-hydroxyphenazone (*o*-Nitro-*p*-cresol); *Process for preparing —*. Farbwerke vorm. Meister, Lucius, and Brüning. Ger. Pat. 206,638, Oct. 24, 1907.

p-CRESOL carbonate is obtained by the action of phosgene on the alkali derivatives of *p*-cresol, by nitration and saponification of the product, *o*-nitro-*p*-cresol, of m. pt. 77° C., is obtained in good yield. It could formerly only be prepared by diazotisation of *o*-nitro-*p*-toluidine, and subsequent decomposition.—T. F. B.

Santalol esters. G. W. Johnson, London. From Verein. Chemfabr. Zimmer und Co., Frankfurt, Germany. Eng. Pat. 15,122, July 16, 1908.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

Metol [*metol* (*metol* *pyraminophenol* *sulphate*)]; *Analysis of —*. A. Nicolle. Monit. Scient., 1909, 23, 173.

COMMERCIAL metol may contain *p*-aminophenol sulphate which interferes with the keeping qualities of the developer, and the following test is described for detecting the presence of this substance. About 1 grm. of the sample is shaken with 3 c.c. of concentrated hydrochloric acid. If, after a few minutes, the solution is not perfectly clear, *p*-aminophenol sulphate is present. Mineral adulterants, such as sulphides, etc., may be detected by incinerating a portion of the sample; in no case should the ash exceed 0.5 per cent.—W. P. S.

PATENTS.

Flash lights; *Mixture for — and method of producing the same*. C. Bethge, Berlin. Eng. Pat. 14,692, July 10, 1908.

MIXTURES for producing flash-lights for photographic and similar purposes consist of a combustible metal such as powdered magnesium or aluminium, and an oxygen carrier composed of insoluble or difficultly soluble compounds of thorium with acids. A suitable mixture consists of 30 to 35 parts of magnesium powder and 70 parts of thorium chromate. A slower burning mixture for time-light exposures consists of 1 part of magnesium powder and 2 parts of thorium tungstate. The compounds of thorium peroxide with nitric, sulphuric, or perchloric acids may also be used. These compounds are obtained by dissolving thorium hydroxide in the corresponding acid, precipitating with an excess of hydrogen peroxide, heating to 60° C., and finally cooling rapidly. The compound thus obtained is mixed with magnesium powder in equal proportions.—A. T. L.

Multicoloured surfaces; Process for preparing — by direct dyeing. Verein. Kunstseidefabr. A.-G. Fr. Pat. 395,165, Oct. 12, 1908. Under Int. Conv., July 23, 1908.

If the surface of a substance such as gelatin or celluloid be partially coloured by immersion in a solution of a dye-stuff and then washed and dried, it is found that by a brief second immersion in a different solution, the uncoloured portion can be dyed, without the shade of the coloured part being affected. It is preferable after the second and any subsequent immersions in a dyeing solution, to wash the material at once in a medium in which it cannot be dyed. Thus celluloid, which cannot be coloured by an aqueous solution, should be rinsed with water, whilst a surface of gelatin or casein should be washed with alcohol. The process may be applied to the preparation of three-colour gratings.—P. F. C.

Light-sensitive surfaces and ferroprussiate papers containing molybdenum; Process for preparing —. Neue Photographische Ges. Ger. Pat. 206,320, May 9, 1907.

DIRECT copying papers are obtained by coating paper with molybdic acid in presence of oxalic acid; these papers are "developed," after exposure to light, by means of a ferricyanide which forms, with the molybdo-molybdate produced, an insoluble, stable, highly coloured image. 18 grms. of molybdenum trioxide are added to a solution of 20 grms. of oxalic acid in 400 c.c. of water; by crystallisation a mixture of oxalic acid and molybdic acid is produced, which can be coated on paper. For blue tones, the developer may contain ferric chloride, potassium ferricyanide, and oxalic acid; for brown tones, uranium nitrate, and for red tones copper sulphate is substituted for the ferric chloride. The sensitiveness of ferroprussiate papers is increased by addition of molybdic acid; thus, paper may be immersed in a solution of 3 grms. of molybdic-oxalic acid mixture, 2.5 grms. of potassium ferricyanide, 0.5 grm. of oxalic acid, 1 grm. of sodium chloride, 12 grms. of ferric ammonium citrate, and 3 grms. of gelatin in 100 c.c. of water; after exposure to light these papers are developed by water.—T. F. B.

Photography in colours; Process for preparing grained screens for —. C. L. A. Brasseur. Fr. Pat. 394,914, Oct. 3, 1908. Under Int. Conv., Oct. 4, 1907.

SEE Eng. Pat. 20,909 of 1908; this J., 1909, 260.—T. F. B.

Screens in two or more colours [for colour photography]; Process for preparing —. Verein. Kunstseidefabr. A.-G. Fr. Pat. 395,164, Oct. 12, 1908. Under Int. Conv., July 13, 1908.

SEE Eng. Pat. 21,839 of 1908; this J., 1909, 260.—T. F. B.

XXII.—EXPLOSIVES, MATCHES, &c.

Chlorate explosion; A peculiar —. G. C. Davis. J. Ind. and Eng. Chem., 1909, 1, 118.

THE author draws attention to the possible danger attending the use of secondhand kegs. On two different occasions explosions occurred in Philadelphia with kegs containing small metal castings. In one case it was proved definitely that the keg had been obtained from a dye-works and had contained potassium chlorate, some of which had evidently remained behind when the casks were cleaned, and formed an explosive mixture with the wood, which became ignited by a spark produced by jolting of the metal castings.—A. S.

White or ordinary phosphorus in the igniting composition of lucifer matches; Detection of —. T. E. Thorpe. Chem. Soc. Proc., 1909, 26, 73—74.

As the White Phosphorus Matches Prohibition Act, 1908, will throw upon Officers of Customs and the Inspectors under

the Factory and Workshop Act, 1901, the duty of sampling importations of matches and of materials in use in match factories, the author has examined the methods by which the presence of ordinary phosphorus in the igniting composition of lucifer matches containing phosphorus sesquisulphide may be established, and he finds that the most direct and most certain test is to isolate the phosphorus as such, which is conveniently effected by gently heating the composition in a vacuum, when the phosphorus sublimes and may be readily recognised by its physical characteristics.

PATENTS.

Explosive, and process of making the same. A. La Motte. Assignor to the E. I. du Pont de Nemours Powder Co., Wilmington, Del. U.S. Pat. 911,019, Jan. 26, 1909.

THE explosive is formed by mixing a molten organic nitro-compound or a mixture of such compounds with a solid inorganic oxidising agent, and adding a metallic sulphide to the solidified mixture. For example, a molten mixture of nitronaphthalene and nitrotoluene is mixed with ammonium nitrate, and after the mixture has hardened, a sulphide, such as pyrites, is added.
—A. T. L.

Nitro-hydrocarbon composition; Process of densifying a —. F. J. H. Roewer, Hamburg, Germany. Assignor to The E. I. du Pont de Nemours Powder Co., Wilmington, Del. U.S. Pat. 912,733, Feb. 16, 1909.

It is proposed to "densify" a nitro-hydrocarbon composition, for use in charging projectiles, by introducing it, in a molten condition, into a previously chilled receptacle. The material is thus subjected to sudden chilling and the pressure due to its own weight.—F. SOHN.

Smokeless powders. Société anonyme d'Explosifs et de Prod. Chim. Fr. Pat. 394,992, Dec. 13, 1907.

CLAIM is made for the use of nitro-derivatives of the fatty series in the manufacture of smokeless powders with a base of nitrocellulose or of nitrocellulose and nitroglycerin. In particular mononitromethane (b. pt. 99°—100° C.), may be used as the solvent in the preparation of powerful and very stable smokeless powders. When employed in admixture with nitroglycerin, these nitro-derivatives yield products of low freezing point. Thus nitroglycerin containing 10 per cent. of mononitromethane does not freeze at -15° C. They may also be used in admixture with other substances (e.g., alcohol, ether, acetone) to effect the gelatinisation of nitrocellulose.
—C. A. M.

Nitroglycerin; Process of manufacturing —. F. Aigner, Potsdam. Assignor to Dynamit A.-G. vorm. A. Nobel and Co., Hamburg. U.S. Pat. 913,653, Feb. 23, 1909.

SEE Fr. Pat. 351,454 of 1905; this J., 1905, 903.—T. F. B.

XXIII.—ANALYTICAL CHEMISTRY.

INORGANIC—QUALITATIVE.

Ferrous salts; New colour reaction for — [with sodium phosphotungstate]. A. Richard and Bidot. J. Pharm. Chim., 1909, 29, 230—234.

A REAGENT is prepared with 25 grms. of sodium phosphotungstate, 5 c.c. of hydrochloric acid, and 250 c.c. of water. A few drops of this, added to a liquid containing minute traces of ferrous iron, and made alkaline with sodium hydroxide solution, develop a deep blue colour resembling that of Fehling's reagent. Ferric iron does not react, and free acids destroy the colour. The reaction is extremely sensitive.—J. O. B.

INORGANIC—QUANTITATIVE.

Arsenic; Precipitation of — by hydrogen sulphide. L. L. De Koninck. *Bull. Soc. Chim. Belg.*, 1909, 23, 88—93.

ARSENIC acid is reduced quickly, and the precipitation of arsenous sulphide accelerated, if, to the strongly acid hydrochloric solution of the arsenic acid, a small quantity of hydroiodic acid be added, before the hydrogen sulphide is introduced. The reduction and precipitation is still further hastened when the solution is heated. The arsenous sulphide is precipitated almost immediately, and the supernatant liquid remains clear; only after a time is sulphur precipitated. Potassium or ammonium iodide may be used in place of hydroiodic acid.—W. P. S.

Cyanous acid in copper. Cofletti. *See X.*

Nitrites in water. Rochaix. *See XVIII B.*

ORGANIC—QUALITATIVE.

Benzene and salicylic acids; Detection of — in fermented beverages and milk. L. Robin. *Ann. Chim. analyt.*, 1909, 14, 53—54.

THE author's test for the detection of benzoic acid in fats (this J., 1908, 1171), which depends on its conversion into *m*-dinitrobenzoic acid and then into ammonium *m*-aminobenzoate, is equally applicable for the detection of this preservative in beverages and milk. The test may be combined conveniently with the test for salicylic acid. In the case of wines, ciders, and beers, 50—60 c.c. of the liquid are treated with a little ferric chloride and hydrochloric or sulphuric acid. The liquid is then shaken with 40—50 c.c. of ether, the ethereal extract is separated and washed, and then divided into two portions. One portion is employed for the usual test for salicylic acid; the other half is shaken with 25 c.c. of an alcoholic solution of sodium bicarbonate. The alkaline solution is evaporated on the water-bath and the residue is tested for benzoic acid by the method described, *loc. cit.* In the case of milk it is necessary to remove the casein and cream. For this purpose, 10 c.c. of 5 per cent. sulphuric acid and 20 c.c. of 95 per cent. alcohol are placed in a beaker, and 50 c.c. of the milk are delivered into the mixture in a fine stream, the contents of the beaker being stirred continuously during this operation. The precipitate is allowed to stand for 5 minutes and is then poured on a filter, the filtrate being returned until it comes through perfectly bright. The filtrate is then placed in a separating funnel with 50 c.c. of ether. Since the mixture emulsifies very readily, it is advisable to fill the funnel completely by the addition of water before proceeding to shake. The ethereal extract is separated, washed, divided into two portions and tested for salicylic and benzoic acids respectively.—J. E. B.

ORGANIC—QUANTITATIVE.

Organic matter; Experiments on Gasparini's electrolytic process for the destruction of — in chemical-legal analysis. M. Miorandi. *Gaz. chim. ital.*, 1909, 39, I, 175—179. (See this J., 1904, 952; 1908, 340.)

ATTEMPTS to substitute carbon electrodes (with an electrolyte containing hydrogen peroxide or ammonium persulphate) for the platinum electrodes used by Gasparini proved unsuccessful. Very satisfactory results were, however, obtained, using platinum electrodes, when nitric acid as oxidising agent was replaced by a super-

saturated solution (60 per cent.) of ammonium persulphate, the electrolysis being conducted at 56° C. with a current of 3.75 amperes. The use of ammonium persulphate offers the advantage that the solution remains alkaline during the greater part of the process.—A. S.

Hydroxyl derivatives in mixtures of organic compounds; Determination of —. H. Hibbert. *Chem. Soc. Proc.*, 1909, 25, 57.

HIBBERT and Sudborough's method (*Chem. Soc. Trans.*, 1904, 85, 933, and this J., 1904, 77) for the estimation of hydroxyl groups in carbon compounds can be applied with equal success to mixtures of hydroxyl derivatives with other organic compounds, for example, ketones, esters, nitriles, etc. It is necessary to take rather more of the Grignard reagent than is sufficient to combine with both substances. In this way the author has been able to estimate *n*-naphthol in presence of various ketones, ethyl benzoate, methyl hydrogen succinate, and acetonitrile, as well as chloral in a mixture of this with acetone.

XXIV.—SCIENTIFIC & TECHNICAL NOTES.

Emulsification; The theory of —. C. R. Marshall. *Pharm. J.*, 1909, 82, 257—266.

THE author made experiments on the emulsifying power of gum acacia, soap, saponin, condensed milk, sugar, and barium sulphate. A primary emulsion of almond oil, water, and the emulsifying agent was first prepared in a mortar, and further small quantities of oil were then added until the emulsion refused to take up more. After now incorporating a definite quantity of water, more oil was added, and these alternate additions of water and of oil were continued as long as desired or until the emulsion broke. The results are plotted in curves with the volumes of oil as ordinates and the volumes of water as abscissæ; in most cases the curves approximate to straight lines. As typical of the results obtained, it may be stated that to emulsify 200 c.c. of almond oil, there are required: 10 grms. of gum acacia and 23 c.c. of water, 1 gm. of soft soap and 3.8 c.c. of water, 0.2 gm. of saponin and 9.6 c.c. of water, 5 grms. of condensed milk and 20 c.c. of water. Also, 1 gm. of gum acacia and 4 c.c. of water will emulsify 21 c.c. of almond oil, 1 gm. of soft soap and 4 c.c. of water will emulsify 210 c.c. of oil, and 0.2 gm. of saponin and 4 c.c. of water will emulsify 90 c.c. of oil. All of the experiments were made at 13° C. In another set of experiments a definite percentage of oleic acid was added to paraffin oil and after running in excess of *N* 10 potassium hydroxide solution, and emulsifying by means of twenty strokes of a syringe, the mixture was allowed to settle, and the volume of emulsified paraffin oil observed. No differences were observed between oils containing 1 per cent. and 0.01 per cent. respectively of oleic acid. When the proportions of oleic acid were 0.01, 0.005, 0.0025, 0.00125, and 0.00065 per cent. respectively of oleic acid, and *N*/100 potassium hydroxide solution was used, the volumes of emulsified

paraffin oil were 3, 2.3, 2, 1.5, and 1.4 c.c. Oil of turpentine, owing to its low surface tension, is difficult to emulsify. It is practically impossible, for instance, to prepare an emulsion of turpentine oil and white of egg directly in a mortar. If, however, the white of egg be first diluted with water and emulsified with the turpentine oil by means of a syringe, then a large quantity of turpentine oil can subsequently be incorporated by means of a pestle and mortar in the ordinary manner. After discussing the views of Ramsden and Pickering (see this J., 1908, 88), the author points out that the theory adopted by Pickering, according to which the globules of the emulsified substance are enveloped in a coating of minute solid particles, does not possess sufficient experimental support to account for gum emulsions, emulsions of mercury with oil, and soap emulsions. With regard to de-emulsification, this does not appear to be caused by an increase of temperature within reasonable limits, although in many cases it is facilitated thereby, owing to the effect on the surface tension. The author does not believe that heavy trituration tends to retard emulsification owing to the heat developed by the friction.—A. S.

Gold chloride: Reaction of — with aluminium [colloidal gold]. Dauvé. J. Pharm. Chim., 1909, 29, 241.

WHEN a small piece of aluminium foil is immersed in gold chloride solution for some hours, a portion of the gold is displaced in the colloidal state, giving a fine purple solution when viewed by transmitted, but dull yellow with reflected light. Since iron is invariably present in aluminium, it may take part in the reaction. In presence of excess of aluminium chloride, no reaction occurs.—J. O. B.

Colloids: Apparent diffusion of —. Porosity of colloidal membranes. R. E. Liesegang. Z. Chem. Ind. Kolloide, 1909, 4, 62—63.

A SILVER chloride-collodion emulsion, containing a slight excess of lithium chloride, was prepared from silver nitrate and lithium chloride, spread in a thin film on glass and dried without warming. After some weeks the appearance of the film had completely altered: the silver chloride had become so coarse in grain that the film was opaque, and this coarse-grained silver chloride was entirely on the surface of the film, so that it could be wiped off with the finger. According to the author the pores filled with ether-alcohol in the original collodion had been filled by displacement with water containing a little lithium chloride. This had dissolved silver chloride and carried it to the surface; here the latter salt was deposited in granular form and the lithium chloride set free wandered back into the film and dissolved more of the finely-divided silver chloride, which, being more finely divided, had a greater solution-tension; the process was then repeated indefinitely.—E. F.

Freezing of jellies. G. Bruni. Ber., 1909, 42, 563—565.

COLLOIDAL jellies of isinglass, as a typical reversible colloid, and of silicic acid, a typical irreversible colloid, were frozen and remelted. The isinglass jelly thawed as a whole, and the thawed jelly showed no physical change. The silicic acid, on the other hand, was completely precipitated in small amorphous scales, as already described by Lottermoser (this J., 1908, 1224). These scales, as obtained from jellies containing from 2.9 to 17.72 per cent. of silica, vary in composition from $\text{SiO}_2 + 0.788\text{H}_2\text{O}$ to $\text{SiO}_2 + 3.67\text{H}_2\text{O}$. These figures correspond to the limits found by Van Bemmelen for the absorption of moisture by dehydrated silica. The amount of water in the precipitate obtained by freezing does not appear to stand in any constant relation to the amount of silicic acid in the original jelly, but appears to be affected by the age of the jelly.—E. F.

Light-reactions of white and yellow diphenyloctatetrene. H. Stobbe. Ber., 1909, 42, 565—568.

WHITE diphenyloctatetrene has been obtained by the condensation of cinnamic aldehyde and ethyl succinate in

presence of sodium ethylate; it melts at 124°C. Yellow diphenyloctatetrene has been obtained in a similar manner by the action of acetic anhydride on a mixture of cinnamic aldehyde and sodium succinate; it melts at 225°C. The author considers these compounds to be probably structural isomerides. The yellow compound is decomposed by light in presence of air with formation of a gummy mass, both in solution and in the solid state; in the latter case some benzaldehyde and benzoic acid are formed. In the dark it is unaffected by air. In the absence of air the yellow compound is partially converted into the white variety by the action of sunlight, both in solution (in chloroform containing iodine) and in the solid state. The white compound, when acted on by light in presence of air, is decomposed with formation of benzaldehyde and benzoic acid in the same manner as the yellow isomeride. In the absence of air it is not changed into the yellow variety on exposure to light.—E. F.

New Books.

DIE BEDEUTUNG DER KOLLOIDE FÜR DIE TECHNIK. Allgemeinverständlich dargestellt von Professor Dr. KURT ARNDT. Theodor Steinkopff's Verlag. Dresden. 1909. Price M L.

340 volume, containing table of contents, preface, and 34 pages of subject matter. The subjects chiefly treated of are as follows:—I. Colloid; definition of the term. II. Colloid solutions. III. Colloid metallic solutions. IV. Coagulation of colloid solutions. V. Reversible and irreversible colloids. VI. Ruby-red gold glass. VII. Milk glass, &c. VIII. Silver- and gold mirrors on glass. IX. Tungsten lamps. X. Colloids in the ceramic industry; in cements; and as glues and similar agglutinants. XI. Liquid absorbents. XII. Diaphragms and filters. XIII. Adsorption. XIV. Lake formation. XV. Dyeing. XVI. Tanning. XVII. Soap boiling. XVIII. Consistent machine fats. XIX. Purification of sewage. XX. Colloids and the cultivation of the soil.

SYSTEMATIC TREATMENT OF METALLIFEROUS WASTE. L. PARRY. The Mining Journal, London. 1909. Price 5s. net.

3vo volume, containing 121 pages of subject matter with eight illustrations. The text is subdivided and classified as follows:—I. General economic principles. II. Sources of supply. Kinds of waste. III. General chemical and metallurgical principles. IV. Partial or semi-refining. V. Smelting of lead ashes and the cleaning of tin slags. VI. Smelting of tin ashes and solder ashes. VII. Smelting of antimonial material. VIII. Separation of copper from tin, and lead from antimony. IX. Copper work. X. Miscellaneous. XI. Metal working and refining.

TABELLEN FÜR BERECHNUNG VON KALIANALYSEN. Herausgegeben von Dr. R. EHRHARDT. Wilhelm Knapp's Verlag. Halle a. S. 1908. Price M 3.00 net.

8vo volume, containing 69 pages of subject matter, which consists of tables for the calculation of analyses required in the potash-, caustic potash-, and nitre industries. There are in all seven tables of factors, and the mode of using them and the factors they contain, in the calculations required, is explained in the preface.

DAS AMMONIAK UND SEINE VERBINDUNGEN. Dr. J. GROSSMANN. Wilhelm Knapp's Verlag. Halle a. S. 1908. Price M 3.60.

8vo volume, containing 103 pages of subject matter, with seven illustrations and numerous tables, preface, and table of contents. The subject matter is classified as follows:—I. Ammonia. Historical and

theoretical. Occurrence, preparation, and purification. II. Ammonia solution. III. Liquid ammonia. IV. Ammonium carbonate. V. Ammonium sulphate. Waste gases and liquors in the manufacture, and their treatment, &c. VI. Ammonium chloride. VII. Ammonium nitrate. VIII. Ammonium phosphate, sulphide, fluoride, sulpho cyanide, and ferrocyanide.

THE DYEING AND CLEANING OF TEXTILE FABRICS.
A Handbook for the Amateur and the Professional.
F. A. OWEN. Based partly on notes of H. C. STANDAEE.
John Wiley and Sons, New York, 1909. Price \$2.00 net. Chapman and Hall, Limited, London. 88. 6d. net.

SMALL. 8vo volume, containing 241 pages of subject matter, and an alphabetical index. The matter may be designated a collection and classified selection of recipes for the cleaner, bleacher, and dyer of textile fabrics, as well as, to a certain extent, other materials. An alphabetical and classified index of all the principal dyestuffs is given and finally, other particulars are added in abbreviated form, as taken from Metz and Co.'s Year Book, 1907.

HEAT ENERGY AND FUELS. PYROMETRY COMBUSTION. ANALYSIS OF FUELS AND MANUFACTURE OF CHARCOAL, COKE, AND FUEL GASES. HANNS V. JÜPTNER, Professor, Imperial and Royal Tech. Inst., Vienna. Translated by OSKAR NAGEL, Ph.D. McGraw Publishing Company, 239, West 39th Street, New York, 1908. Price \$3 net.

LARGE. 8vo volume, containing 301 pages of subject matter, with 118 illustrations, and an alphabetical index. The subject matter is classified as follows:—INTRODUCTION: (i). General Remarks. (ii). Forms of energy. **HEAT ENERGY AND FUELS:** I. Measurement of high temperatures (pyrometry). II. Optical methods of measuring temperatures. III. Combustion heat and its determination. IV. Direct methods for its determination. V. Incomplete combustion. VI. Combustion temperature. VII. Fuels (generally). VIII. Wood. IX. Fossil solid fuels. X. Peat. XI. Lignite. XII. Bituminous and anthracite coals. XIII. Artificial solid fuels. XIV. Charcoal. XV. Peat-coal, coke, and briquettes. XVI. Coking apparatus. XVII. Liquid fuels. XVIII. Gaseous fuels. XIX. Producer gas. XX. Water gas. XXI. Dowson, and Blast-furnace gases, and Regenerator combustion gases. XXII. Apparatus for the production of Fuel Gases.

MINERAL RESOURCES OF THE UNITED STATES, 1907.
U.S. Geological Survey, Washington.

THIS is the Annual Report of the Geological Survey on the mineral resources of the United States. It is divided into two parts. Part I contains an account of the metals and metallic ores produced in 1907, and part 2 consists of details relative to fuels, structural materials, abrasive materials, chemical materials (e.g., arsenic, borax, salt, sulphur), pigments, and "miscellaneous" (including asbestos, graphite, etc.).

Patent List.

Where a Complete Specification accompanies an Application, an asterisk is affixed. The dates given are (i) in the case of Applications for Patents, the dates of Application, and (ii) in the case of Complete Specifications Accepted, those of the Official Journals in which acceptances of the Complete Specifications are advertised.

Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

I.—PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

5285. Bristow and White. Apparatus for drying powdered or granular material. March 4.

5362. Herring. *See under X.*

5395. Soc. l'Air Liquide. Recovery of vapours of volatile liquids, particularly alcohol and ether, from their admixture with air. [Fr. Appl., March 6, 1908.]* March 5. 5619. Gill. *See under VII.*

5647. Griffin. Evaporating and distilling apparatus operated by the hot exhaust gases of internal combustion engines. March 9.

5735. Yates, and Matthews and Yates, Ltd. Centrifugal separators. March 10.

5931. Lévy. Separation of gaseous mixtures into their constituents. March 11.

COMPLETE SPECIFICATIONS ACCEPTED.

27,017 (1907). Hommel and others. *See under X.*

2029 (1908). Tavernier. Separation of gases of different densities, especially for increasing the proportion of oxygen in air. March 10.

5187 (1908). Schmatolla. Gas-fired kilns. March 17.

6253 (1908). Lewis, and High Moor Synd., Ltd. Apparatus for separating materials of different specific gravities. March 10.

14,444 (1908). Alford. Power filter press. March 10.

25,213 (1908). Leclaire and Hericourt. Filter. March 17.

27,245 (1908). Normac-Gie, Ges., and Kirner. Pyrometers. March 17.

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

4973. McKay and Cheney. Water-gas generators. [U.S. Appl., Nov. 11, 1908.]* March 1.

5010. Rhenania Glühlicht Comp. Incandescent mantles for gas lighting. [Ger. Appl., Feb. 6, 1909.]* March 1.

5063. Robin. Manufacture of incandescent gas mantles.* March 2.

5260. Fellner (Oberfeldt und Co.). Incandescent gas mantles.* March 4.

5408. Collin. *See under VII.*

5412. Ward. *See under XXIII.*

5463. Severin. Manufacture of incandescent gas mantles.* March 6.

5836. Crossley. Incandescent gas mantles. March 11.

COMPLETE SPECIFICATIONS ACCEPTED.

4529 (1908). Maly. Gas generators. March 10.

11,688 (1908). Mueller. Regenerative coke ovens. March 10.

14,867 (1908). British Thomson-Houston Co. (General Electric Co.). Manufacture of incandescent lamp filaments. March 10.

17,596 (1908). Von Unruh. Manufacture of incandescent bodies for gas lighting. March 10.

17,620 (1908). Coolidge. Manufacture of refractory electric conductors suitable as filaments for lamps. March 17.

23,992 (1908). Knappich. Increasing the calorific value of coal-gas. March 17.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, PETROLEUM, AND MINERAL WAXES.

APPLICATIONS.

5552. Luis. Enriched hydrocarbons. March 8.

5731. Adamson (Burmah Oil Co., Ltd., and Campbell). Treating or purifying paraffin wax. March 10.

6081. Claussen and Moore. Process for obtaining deodorised oil mixtures from naphtha, petroleum, or other mineral oils. March 13.

COMPLETE SPECIFICATION ACCEPTED.

27,335 (1907). Everett. Production of by-products from asphaltum, etc. March 17.

IV.—COLOURING MATTERS AND DYESTUFFS.

APPLICATIONS.

4963. Newton (Bayer and Co.). Manufacture of dyestuffs of the galloxyaniline series. [Addition to No. 20,368 of 1908.] March 1.

5022. Smiles and Barnett. Dyestuffs obtained from nitrodiphenylamine sulfoxides. March 1.

5382. Newton (Bayer und Co.). Manufacture of derivatives of the anthracene series. March 5.

5383. Newton (Bayer und Co.). Manufacture of azo dyestuffs. March 5.

5558. Inray (Meister, Lucius, und Brüning). Manufacture of leuco-bodies of dyestuffs containing sulphur. March 8.

5786. Newton (Bayer und Co.). Manufacture of dyestuffs of the anthraquinone series. March 10.

5792. Soc. pour l'Ind. Chim. à Bâle. Manufacture of substantive azo dyestuffs. [Addition to No. 6814 of 1907. Fr. Appl. March 11, 1908.]* March 10.

5998. Newton (Bayer und Co.). Manufacture of derivatives of the anthraquinone series. March 12.

6086. Bloxam (Act.-Ges. f. Anilinfabr.). Manufacture of monoazo dyestuffs. March 13.

COMPLETE SPECIFICATIONS ACCEPTED.

4624 (1908). Fowler. *See under A.*

4848 (1908). Bloxam (Chem. Fabr. Griesheim Elektron). Manufacture of brown sulphurised dyestuffs. March 10.

10,755 (1908). Newton (Bayer und Co.). Manufacture of red vat colouring matters containing sulphur. March 10.

20,003 (1908). Basler Chem. Fabr. Manufacture of vat dyestuffs. March 17.

V.—PREPARING, BLEACHING, DYEING, PRINTING, AND FINISHING TEXTILES, YARNS, AND FIBRES.

APPLICATIONS.

5075. Bartelt. Employment of sodium hypochlorite and analogous products for laundry purposes. March 2.

5575. Maly. Dyeing woollen yarn on bobbins.* March 8.

5721. Cuming. The dressing of vegetable fibres. March 10.

5734. Marshall. Apparatus for dyeing and similarly treating textile material on bobbins or the like. March 10.

5771. Rumpf. Production of a water- and soap-proof gloss on woven materials of cotton. March 10.

5859. Vandatte and Lagye. Electrical process and apparatus for removing the grease and yolk from wool.* March 11.

6034. Robertson. Calico printing machines. March 13.

COMPLETE SPECIFICATIONS ACCEPTED.

4624 (1908). Fowler. Dyeing and dyes for use therein. March 10.

6893 (1908). Kershaw, Abell, and Leach. Dyeing, scouring, and analogous machines. March 17.

9579 (1908). Claessen. Dressing fibres and fabrics, and manufacture of paper, wood pulps, etc. March 10.

11,314 (1908). Newton (Bayer und Co.). Printing. March 10.

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

5293. Pape. Preparation of zinc oxide for education.* March 4.

5408. Collin. Recovering ammonia from coal gases. March 5.

5472. Bender. Manufacture of oxides of nitrogen. March 6.

5618. Gill. Manufacture of ferric oxide. March 9.

5619. Gill. Reverberatory furnaces for calcining hydrated oxides of iron and other materials. March 9.

5799. Cie. Gén. d'Electro-Chimie de Bozel. Manufacture of metallic silicides. [Fr. Appl., March 31, 1908.]* March 10.

5821. British Thomson-Houston Co. (General Electric Co.). *See under X.*

6009. Nielsen. Manufacture of carbonate of soda. March 12.

COMPLETE SPECIFICATIONS ACCEPTED.

2029 (1908). Tavernier. *See under I.*

4515 (1908). Rivière. Manufacture of hydrofluosilicic acid. March 10.

4750 (1908). Schäcke. Manufacture of hydrates of potassium and of sodium from recent eruptive stones. March 10.

6449 (1908). Morris. *See under XI.*

8959 (1908). May and Baker, Ltd., and Bates. Mercury compound and method of manufacturing the same. March 17.

12,743 (1908). Goldschmidt. Separation and concentration of chlorine. March 10.

12,812 (1908). Watson, Ashall, and United Alkali Co. Manufacture of copper sulphate. March 10.

14,707 (1908). Peniakoff. Manufacture of alkaline aluminates. March 10.

21,255 (1908). Oddo. Furnaces for the combustion of sulphur. March 17.

23,330 (1908). Sorger. *See under XX.*

VIII.—GLASS, POTTERY, AND ENAMELS.

APPLICATIONS.

5722. West and Lewis. Potters' kilns or ovens for firing bricks, tiles, etc. March 10.

6022. Nielsen. Washing and separating china and other clays, earth pigments, etc. March 12.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

5277. Hogg. Manufacture of Portland cement. March 4.

5908. Chisolm. Method of treating wood. March 11.

COMPLETE SPECIFICATIONS ACCEPTED.

4929 (1908). Chateau and Merklen. Impregnation and preservation of wood. March 10.

14,342 (1908). Berner, Frankl, and Mendelsohn. Manufacture of artificial stone. March 10.

X.—METALS AND METALLURGY.

APPLICATIONS.

5007. De Benedetti. Platinum solder. March 1.

5013. Taylor. Apparatus for separating gold and other metals from dust and other impurities. March 1.

5350. Hales. Manufacture of iron and steel. March 5.

5362. Herring. Carbonising and otherwise treating minerals or other substances. March 5.

5675. Boulton (Newell Manufacturing Co.). Metallisation of non-metallic articles.* March 9.

5712. Fennell and Sackett. Purification of molten metals.* March 9.

5802. Simpson and Oviatt. Metallurgy of iron and steel. March 10.

5821. British Thomson-Houston Co. (General Electric Co.). Reduction of oxides.* March 10.

6088. Aktiebolaget Electrometall. *See under XI.*

COMPLETE SPECIFICATIONS ACCEPTED.

27,017 (1907). Hommel, and Metals Extraction Corporation. Apparatus for use in solution and precipitation processes. March 17.

27,018 (1907). Hommel, and Metals Extraction Corporation. Furnaces for volatile metals. March 17.

27,020 (1907). Hommel, and Metals Extraction Corporation. Extraction of zinc from ores or zinc residues. March 17.

5515 (1908). Jones. Treatment of ores. March 17.

7584 (1908). Nodon. Recovery of tin from waste tinned metal, alloys, etc. March 17.

12,322 (1908). Boulton (Jones). Treatment of iron ore. March 10.

12,342 (1908). Holzapfel. Crucible furnaces. March 10.

12,750 (1908). Carrick and Pattison. Treatment of copper mattes. March 17.

18,523 (1908). Schmelzer. Metallurgical furnaces. March 10.

23,958 (1908). Souard. Cementation of iron, steel, etc. March 10.

531 (1909). De Ferranti. Manufacture of material suitable for the blading of turbines, compressors, etc. March 10.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

APPLICATIONS.

5958, 5960 and 5962. Gibbs. Producing metallic articles by electrodeposition. [Comprised in No. 4410. Feb. 27, 1908.] March 12.

6088. Aktiebolaget Elektrometall. Electric production of iron and steel and other metals and furnaces therefor. [Swed. Appl., Aug. 1, 1908.]* March 13.

COMPLETE SPECIFICATION ACCEPTED.

6449 (1908). Morris. Electrolytic production of aluminium oxide. March 17.

XII.—FATTY OILS, FATS, WAXES, AND SOAPS.

APPLICATIONS.

4956. Gilbert and Ralph. Machines for cooling soaps, fats, etc. March 1.

5050. Bamberg. Hydrolysis. March 2.

5620. Macpherson and Heys. Detergent and emulsive agent. March 9.

5715. Budde and Robertson. Decomposition of fats and oils into fatty acids and glycerin. March 9.

5797. Common and Hull Oil Manufacturing Co. Manufacture of soya bean oil. March 10.

COMPLETE SPECIFICATIONS ACCEPTED.

16,642 (1908). Lanerman. Apparatus for extracting oil. March 17.

22,441 (1908). Rinze. Manufacture of albumose soap. March 10.

XIII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, Etc.

(A.)—PIGMENTS, PAINTS.

APPLICATION.

6022. Nielsen. *See under VIII.*

COMPLETE SPECIFICATION ACCEPTED.

11,638 (1908). White. Production of oxide of iron pigments. March 10.

(B.)—RESINS, VARNISHES.

APPLICATIONS.

5709. Yaryan. Purification of resin.* March 9.

5978. Ogilvie and Mitchell. Obtaining oleo-resins from wood. March 12.

XIV.—TANNING, LEATHER, GLUE, SIZE, Etc.

COMPLETE SPECIFICATIONS ACCEPTED.

12,799 (1908). Nance. Process and apparatus for tanning and treating hides and skins. March 17.

14,256 (1908). Schmitt and Ahrens. Drying albumen. March 17.

XV.—MANURES, Etc.

COMPLETE SPECIFICATION ACCEPTED.

4753 (1908). Schäcke. Manufacture of manure from recent eruptive stones containing potassium protoxide and lime salts. March 10.

XVII.—BREWING, WINES, SPIRITS, Etc.

APPLICATIONS.

5395. Soc. l'Air Liquide. *See under I.*

5571. Ascoli. Medicinal preparation from yeast. [Addition to No. 21,820 of 1908.]* March 8.

5790. Haack. Maturing and purifying alcoholic liquors. [Fr. Appl., March 11, 1908.]* March 10.

6087. Valentin. Mashing malt for brewing. March 13.

COMPLETE SPECIFICATIONS ACCEPTED.

1884 (1908). Breker. Brewing processes. March 10.

6396 (1908). McDougall. Distillation of whisky. March 17.

XVIII.—FOODS; SANITATION, WATER PURIFICATION; AND DISINFECTANTS.

(A.)—FOODS.

APPLICATION.

5562. Lamouroux. Process for obtaining vinegar from whey. March 8.

COMPLETE SPECIFICATION ACCEPTED.

14,256 (1908). Schmitt and Ahrens. *See under XIV.*

(B.)—SANITATION; WATER PURIFICATION.

APPLICATION.

5676. Schultze. Purification of water.* March 9.

XIX.—PAPER, PASTEBOARD, Etc.

COMPLETE SPECIFICATIONS ACCEPTED.

9579 (1908). Claessen. *See under V.*

25,183 (1908). Curtius und Co. Agent for use in sizing paper. March 10.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENTIAL OILS, AND EXTRACTS.

APPLICATIONS.

4967. Penschuck. Production of a disemulsified extract of Casearia sagrada. March 1.

5050. Bamberg. *See under XII.*

5395. Soc. l'Air Liquide. *See under I.*

5571. Ascoli. *See under XVII.*

5773. Pharmazeutisches Institut L. W. Gans. Serum or antitoxin. [Ger. Appl., March 11, 1908.]* March 10.

COMPLETE SPECIFICATIONS ACCEPTED.

4712 (1908). Busch. Manufacture of soluble compounds of hexamethylenetetramine and mercuric salts. March 10.

8514 (1908). Zimmermann (Chem. Fabr. auf Actien, vorm. E. Schering). Manufacture of a pancreas preparation suitable for treating diabetes. March 17.

23,330 (1908). Sorger. Manufacture of therapeutically valuable iron salts. March 17.

3021 (1909). Meister, Lucius, und Brüning. Manufacture of optically active *o*-dioxyphenylalkamines. March 17.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

COMPLETE SPECIFICATION ACCEPTED.

20,971 (1908). Christensen. Manufacture of colour plates or screens for colour photography. March 10.

XXIII.—GENERAL ANALYTICAL CHEMISTRY.

APPLICATION.

5412. Ward. Apparatus automatically indicating and recording the percentage of carbon dioxide in the combustion gases of boiler flues, etc. March 5.

ANNUAL GENERAL MEETING.

NOTICE IS HEREBY GIVEN that the Annual General Meeting of the Society will be held in the Jehangier Hall, Imperial Institute Buildings, London, S.W., at 10.30 in the morning of Wednesday, May 26th next.

In accordance with the provisions of By-law 24, Notice is hereby given that those members whose names are printed in *italics* in the list of Council will retire from their respective offices at the forthcoming Annual Meeting.

Prof. Ira Remsen has been nominated to the office of President under By-law 20; Dr. G. Beilby, F.R.S., Mr. E. Grant Hooper, and Dr. R. Messel, have been nominated Vice-Presidents under By-law 21, and Prof. R. Meldola has been nominated a Vice-President under By-law 20. Mr. Thomas Tyrer has been appointed Hon. Treasurer, and Dr. L. Mond, F.R.S., Hon. Foreign Secretary, under By-law 35.

Members are hereby invited to nominate, on or before April 22nd next, fit and proper persons to fill four vacancies among the ordinary members of the Council under By-law 24. Forms for this purpose can be obtained, on application, from the Secretary of the Society.

By-law 23:—An ordinary member of Council shall be nominated by ten or more members upon Form B in

the Schedule, a copy of which form shall be furnished by the Secretary upon the written or verbal request of any member, but a member shall not be eligible to sign more than one such nomination form, and the member nominated shall sign the declaration set forth on the form. A nomination shall be declared invalid by the Council if:

- The member thereon nominated is disqualified for election, or ineligible to be elected, as provided by the By-laws.

- The nomination is not made on the authorised printed form or substantially not in the manner directed thereon.

- The nomination form is signed by less than ten members not disqualified or not ineligible to nominate as provided by the By-laws.

- The nomination form is not received before or upon the day appointed therefor.

- The member nominated has not signed the declaration printed upon the form.

A member whose nomination aforesaid is declared to be invalid shall receive notice thereof from the Secretary, and shall not be submitted for election.

Notice is also given under the provisions of By-law 38 that the Regulations set forth below will be submitted for consideration and confirmation by the members assembled at the same meeting.

CHARLES G. CRESSWELL,
 Secretary.

DRAFT REGULATIONS

TO BE SUBMITTED TO

THE ANNUAL GENERAL MEETING

FOR CONFIRMATION.

(Under By-Law 38.)

MEMBERS.

- At whatever period of the year a new Member may be elected he shall be required, unless the Council shall determine otherwise, to pay his subscription for that year; having done which he shall be entitled to receive all the numbers of the Society's Journal for that year. (*c.f.* By-law 7.)

- If a Member who has been duly elected, and has paid an Entrance Fee and one or more subscriptions, resigns under By-law 14, and later seeks re-election, the Council may re-admit him without further Entrance Fee.

ANNUAL GENERAL MEETING.

- When a ballot is required under By-law 26, then at such stage in the proceedings of the Annual General Meeting as shall be most convenient, the Members present shall hand their Ballot Lists to the General Secretary, or, in his absence, to such other person as the President may appoint. Members unable to attend the Meeting may send their Ballot Lists before the Meeting to the General Secretary in sealed envelopes. Each such sealed envelope must be marked "BALLOT LIST," and must, moreover, have written upon it the name of the Member sending it. The names written upon such sealed envelope having been compared with the Society's Register by the General Secretary, such sealed envelopes shall be opened at the Meeting by Scrutators appointed by the Meeting. The Scrutators shall see that the conditions of the Ballot are strictly fulfilled. Any Member shall be at liberty to strike out any name or names of Ordinary Members of Council printed on his voting paper.

COMMITTEES.

- No Special Committee, nor any Committee of a Local Section shall have any control over the funds of the Society, except to the extent to which funds for its use may be voted by the Council. An account of the manner in which any funds so voted for the use of any Committee have been expended shall be furnished to the Council on or before the 15th of November in each year.

LOCAL SECTIONS.

5. All elections to the Committee of a Local Section and all elections of Officers of the Section, with the exception of those to fill up unforeseen vacancies, shall take place so that they can be reported to the Council in time to be considered at the Meeting held under By-law 24 not less than two months prior to the Annual General Meeting; but the Members of Committee and Officers thus elected shall not take office and those whom they are to succeed shall not retire from office until the close of the Annual General Meeting aforesaid.

CHARLES G. CRESSWELL,
Secretary.

Canadian Section.

Meeting held at Montreal on Friday, January 22nd, 1909.

MR. ANTHONY MCGILL IN THE CHAIR.

THE INFLUENCE OF ENVIRONMENT ON THE COMPOSITION OF WHEAT.

BY FRANK T. SHUTT, M.A., F.L.C.

In 1908, the output of wheat from the three provinces, Manitoba, Saskatchewan, and Alberta, was 106,000,000 bushels from 6,000,000 acres, valued at \$87,000,000. In 1902 the acreage in wheat was 2,665,698 acres with a yield of 67,000,000 bushels. The estimate for 1909 is 12,000,000 acres in cereals, of which 7,000,000 acres will be wheat. At this rate of increase in the occupation of the Canadian North-Western lands, it might be asked, shall we not very soon exhaust the area available for wheat growing? I think not. There are in the three western provinces, it is estimated, about 170,000,000 acres suitable for cultivation, the greater part of which is undoubtedly adapted to wheat growing. Seeing that only between 5 per cent. and 6 per cent. of this area is at present under tillage, the possibilities for expansion in wheat production are enormous. Dr. Wm. Saunders, Director of the Dominion Experimental Farms, considers the possible wheat production of the three western provinces to be 800,000,000 bushels, one-fourth of the land only being devoted to this cereal annually. But this is not all. To the north of Alberta and Saskatchewan, within the boundaries of Athabasca and MacKenzie, are nearly 500,000,000 acres, and wheat can be grown successfully at a number of points throughout this large area. Wheat has been ripened, for instance, at Dunvegan and Fort Vermillion on the Peace River, the former 414 and the latter 391 miles north of the latitude of Winnipeg, and still further north at Forts Providence and Simpson on the MacKenzie River, within 5 degrees of the Arctic Circle. Last season 30,000 bushels of wheat were harvested at Fort Vermillion. All the evidence points to the Peace River country and much land even further north as capable of producing wheat of excellent quality.

The influence of environment on the composition of wheat, both as to nitrogen and ash content, is a question that has received much attention from agricultural chemists on both sides of the Atlantic. From the results of these experiments and a careful review of the evidence there seems but one conclusion to draw, that climate is far more potent than soil fertility in influencing the composition of the grain. The percentage of nitrogen—and hence the gluten—in the grain, while particularly susceptible to the influences of climate, is practically unaffected by differences in soil fertility, though, as will be pointed out presently, the soil indirectly, i.e., in its capacity for holding moisture,

may very materially modify the composition of the grain in this respect. Richness of the soil in nitrogen (and this is a distinguishing feature of our North-West soils) has but little effect on the percentage of nitrogen in the grain; many sandy loams of moderate nitrogen-content produce wheat of equal gluten-content with that from heavy loams rich in nitrogen. The researches of Lawes and Gilbert showed that manuring had but little influence on the composition of wheat, but that climatic condition was the chief factor affecting the character of the grain. The fertiliser plots of the Central Experimental Farm, Ottawa, have received now for 20 years all sorts of fertilisers, and, so far, these have not materially affected the composition of the grain. Climatic conditions influence the quality of wheat through the vegetative processes—by shortening or lengthening the time which elapses from the formation of the kernel until it is ripe—the shorter this period the higher the nitrogen content. High temperatures, long days and absence of excessive moisture during the ripening process, undoubtedly hasten the maturation of the grain and increase its percentage of gluten. These are the conditions that prevail in the North-West in those seasons which give the largest proportion of first quality wheat, and in these climatic conditions we have an asset, a factor, fully equal in value and importance towards the production of the finest wheat to that we possess in those fertile prairie soils. The proof for the statement that wheat improves in quality as it reaches its northern limit of growth is neither complete nor altogether satisfactory, but, in so far as it is true, the underlying cause is to be found in the high temperatures, long days and absence of heavy rains that characterise the midsummer months of these northern latitudes—the period when the grain is advancing from that of the "dough" stage to full maturity.

In that newly settled area of Manitoba, the Dauphin district, much of the land before ploughing and seeding must be cleared of scrub, i.e., small trees, shrubs, etc. This is known as "scrub" land, and it was found that grain grown on this newly cleared land was more or less soft and starchy in character. It was further found that as time went on and the land had been under cultivation for a number of seasons, the tendency was for the wheat to improve in quality. The change was, as a rule, gradual, but occasionally it was of a marked character. Apparently this change was in a measure influenced by the nature of the season; in some years there was but little difference between the grain grown on the older and newer lands—seed of the same description being sown on both; in other years the difference was so great as to disguise their common parentage. On the whole the evidence of this tendency to improve is very pronounced.

From the first set of samples from this district in this investigation, obtained in 1905, (a) the wheat as sown gave 11.11 per cent. of protein, (b) as grown as the first crop after "breaking," gave 9.93 per cent., and (c) as grown on soil that had been under cultivation for nine years, gave 12.62 per cent. The results show deterioration and improvement, compared with the parent wheat, confirming the opinion gained from an examination of the samples.

In 1906 the moisture content of the two classes of lands throughout the growing season was determined and a complete analysis of the two soils made. The result showed that the newly broken land contained a considerably higher percentage of moisture throughout the season and especially during the latter part of June and on until the crop was harvested.

In 1906 the parent seed wheat contained 9.93 per cent. protein; as grown on breaking, it gave 10.01 per cent., and as grown on old land, it gave 13.52 per cent. protein. Both the parent wheat and that grown on breaking would be termed soft or piebald; the difference between them in protein content is likewise insignificant, the data being practically within the limit of experimental error.

But between these wheats and that grown on the older land there is a great difference. The latter shows no starchy grains—all, or practically all, the kernels are hard, semi-translucent, and typical of a high grade wheat. And the difference in protein content is very considerable, amounting to 3.5 per cent. The moisture content of the two soils furnishes, I think, the explanation for this improvement.

Moisture content of soils to a depth of 8 inches, Valley River, Man., 1906.

Soil.	May 5th.	May 15th.	May 29th.	June 22nd.	July 13th.	August 2nd.	August 24th.
	per cent.	per cent.	per cent.	per cent.	per cent.	per cent.	per cent.
Breaking	32.96	36.49	33.45	30.49	35.23	30.37	32.84
Old land	22.45	23.39	23.39	21.70	21.24	13.24	18.28

The soil producing the softer wheat (breaking) was throughout the growing season more moist; its percentages of water ranged from 9 to 14 higher than those of the soil giving the harder grain. And it is further to be noted that there was no drying out in the "breaking" soil as the season advanced.

The two plots under experiment adjoined—they were part and parcel of the same area—and their soils would be classed as rich sandy loams. That designated as "breaking" had been cleared and deeply ploughed in the June previous. Throughout the remainder of the season (1905) the surface was frequently and thoroughly cultivated to induce decay of the vegetable fibre and prepare a favourable seed bed. This cultivation had the effect of conserving the moisture, and in a large measure no doubt accounts for the higher percentage of water in this soil during the succeeding season.

The other plot had been cleared and put under cultivation nine years previously. During this period the practice had been two years in grain with the third as summer fallow. Thoroughly representative samples to a depth of eight inches furnished on analysis the following results.

Analysis of (air-dried) soils.

	Breaking soil.	Soil 9 years under cultivation.
	per cent.	per cent.
Moisture	2.98	2.06
Organic and volatile matter	20.90	12.84
Insoluble residue (sand, clay, &c.) ..	51.74	65.07
Oxide of iron and alumina	5.50	10.52
Lime	10.25	3.47
Magnesia	2.44	1.63
Potash	0.14	0.19
Phosphoric acid	0.15	0.13
Soluble silica	0.02	0.02
Carbonic acid, &c., (undetermined) ..	5.88	4.07
	100.00	100.00
Nitrogen in organic matter	0.642	0.371
Available constituents—		
Phosphoric acid	0.0067	0.0067
Potash	0.0166	0.0069
Lime	1.306	0.93

The characteristic feature of these soils is their richness in vegetable matter and nitrogen, and it will be noticed that the percentages of these constituents are very considerably higher in the "breaking" soil. Why this should be so we need not now discuss, though therein lies a very important lesson, but this larger proportion of humus—considered in conjunction with the treatment the land had received during the previous season—readily explains the higher moisture content of the "breaking" soil, since humus enhances a soil's absorptive and retentive capacity.

In potash and phosphoric acid these soils present no striking differences, though in lime the newer soil is much the richer. The data, apart from the relation of humus to moisture content,—throw no light upon our problem. It is interesting, however, to observe that the soil with the higher nitrogen content produced the starchier wheat. This is not mentioned as an example of direct cause and effect, but rather to show that a highly nitrogenous soil does not necessarily mean a highly nitrogenous wheat.

To summarise my explanation—which is of course a tentative one—we may say that the larger amount of moisture in the "breaking" soil prolonged the vegetative processes of the wheat plant, delaying the maturation of the grain. This is probably the more marked on very rich (highly nitrogenous) soils such as we are considering than on soils naturally poor or exhausted by cropping. Early ripening of the wheat, such as is brought about by

the gradual lessening of the supply of the soil moisture (and which must mean the cutting off of the soil's food supply), tends, we are of the opinion, to the production of a hard glutinous wheat, which in a sense may perhaps be considered as in a degree immature or rather not fully developed. On the other hand, prolonged vegetative growth as induced by excessive moisture under the influence of favourable temperatures, defers ripening and allows the further deposition of starch, resulting in a more or less soft kernel.

Red Fife wheat was sown on two areas on the Experimental Farm, Lethbridge, Southern Alberta—a district of sparse precipitation, and consequently where the methods of the so-called "dry" farming are practised—and, where possible, irrigation is employed to obtain good yields. One of these areas was irrigated with the object of ascertaining what effect the added water might have on the quantity and quality of the grain. The season during the earlier months was unusually wet and consequently not favourable to the experiment in hand; nevertheless as the following data clearly show the irrigated soil with its higher water content during the period of the wheat's maturation produced the wheat with the lower percentage of gluten.

LETHBRIDGE, 1908 SERIES:—

" " Grown on irrigated land	13.70
" " " " non-irrigated land	16.37
Between the wheats grown on irrigated and non-irrigated land we notice a difference of more than 2.5 per cent. protein, the richer wheat being from the soil that partially dried out during the ripening period.	
Kharkof, a winter wheat, gave the following data:—	
	Protein. (N x 6.25.)
	per cent.
Kharkof—Grown on irrigated land	12.11
" " " " non-irrigated land	13.12

Here we observe a difference of 1 per cent. protein in favour of the wheat from the non-irrigated land.

The soil moisture determinations made at intervals throughout the season are as follows:—

Moisture content of soils.

	"A" irrigated.	"B" non-irrigated.
	per cent.	per cent.
May 14th, 1908	16.56	15.61
July 15th "	8.78	8.11
August 17th "	10.37	6.38

The single irrigation of plot "A" was made directly after the collection of the soil samples on July 15th. The unusually heavy precipitation during the spring and early summer, already referred to, made irrigation prior to this date undesirable. It is worthy of note that while the moisture content of soil "A" increased, that of "B" decreased during the ripening period of the wheat.

In the case of both spring and winter varieties, therefore, the percentage of protein was considerably higher in the wheats from the soils that were the drier during the ripen-

ing of the grain, adding confirmatory evidence to that obtained in Northern Manitoba, the details of which we have discussed more fully.

From these considerations it seems evident that the quality of the wheat of any season may be largely determined by the character of that season. I think we may argue that if there is a sufficiency of moisture in the month of June to bring the wheat crop to maturity, then we may expect better quality grain if the weeks following are characterised by hot, dry weather, than if the weather during this period is cool and wet.

It would of course be impossible this evening to discuss every phase of this interesting problem; in this address it has been my purpose merely to show how the quality of the grain may be affected by the proportion of soil moisture present during the growth and more particularly the latter part of the growth or period of maturation of the wheat, especially under high temperatures such as usually prevail during the mid-summer and early autumn months in the Canadian North-West. There is, however, before closing, one matter to which I must refer in order to prevent any misunderstanding that might arise from what I have said regarding this falling off in quality of the grain under certain conditions. We must be careful to differentiate between quality of wheat and quality of gluten—the former may be influenced either by the proportion or the nature of the latter. We do not find from our chemical work or that of the cerealist, that the character of the gluten of any particular variety of wheat is materially affected by varying climatic conditions, provided of course the wheat reaches a fair degree of ripeness. It seems to me, therefore, that while the amount of gluten is largely a product of the season, the character of gluten is determined and fixed by the variety. In other words, heredity is the potent and dominating factor influencing quality and environment—using the term in its widest sense—the factor affecting its quantity. If further investigation establishes the correctness of this conclusion, the knowledge will prove of the greatest value, for it will enable us to work in the breeding of new wheats with more directness and better hope of success, and it will be of assistance to the wheat grower by indicating the best varieties to grow and the best methods of culture to follow.

MR. MAX MUSPRATT IN THE CHAIR.

THE MOVEMENT OF GASES IN VITRIOL CHAMBERS.

BY HERBERT PORTER, F.I.C.

During the interval since I exhibited the Model Vitriol Chamber before the Manchester Section on the 30th of April, 1903, many manufacturers have adopted the bottom inlet and centre outlet at the end of chambers, and it has been satisfactorily proved, by practical working, that the results have been of considerable value by the increased make of acid.

The most usual increase is about 25 to 30 per cent., in one case as much as 50 per cent. more acid was made in the same chamber space. In mentioning these increased yields it will be understood that the existing conditions at the time of altering the inlets and outlets would largely affect the result. In some works the connections between chambers were in such a position as to render the efficiency of the chamber very low in acid production, and it is on that account that varying increased yields have been recorded. Another point of interest to be recorded is that from the movement of the gases as shown in the model some kind of data can be obtained as to the proper size of a vitriol chamber. If a chamber is 30 feet high the gases from a bottom inlet will rise about 60 feet from the end

and on reaching the top divide into two portions, one returning and one going forward, as seen in the model and as previously illustrated. It, therefore, shows that the length of a chamber should be about four times its height in order to give full play to the natural movement of the gases. It has been also practically proved that the proper place for admitting steam is under the inlet and over the outlet, and not at the sides of the chamber, where the cooler condensing acid gases are descending. With these inlets and outlets the chambers work more steadily and give indication of any irregularity in time to prevent a more serious disorganisation.

DISCUSSION.

The CHAIRMAN asked whether Mr. Porter had any data or any material for checking the result of water sprays instead of steam: the water being supplied in sprays instead of steam. The latent heat of the steam was so great that it was very difficult to imagine that the same conditions would hold when the water was introduced in the form of spray without any of the latent heat, as it was in the form of an ordinary steam jet. Did not the water spray modify the conditions of the chamber? They appeared to be on the brink of a very great economy in chamber space if they could combine the results of the water spray with a more scientific method of introducing the gases.

MR. EUSTACE CAREY asked if there was much difference in a vitriol chamber where the gases were not inert, and were undergoing rapid reactions; of course there was the evolution of a great deal of heat, which, he imagined, would rather interfere with the various currents. He would also like to know what was the capacity in cubic feet per lb. of sulphur burned per 24 hours, at the commencement and at the end of the make, in the cases where the output was increased from 60/70 to 120 tons a week.

MR. T. W. STUART said he had regularly observed the results of the working of about 100 separate sets of chambers, extending over many years, in which chambers of all sizes and forms were worked in sets of 2 up to 7, in a set tandem, with the connection from the Glover tower made at the top of the first chamber, the ends and the sides near the ends, and from 1 up to 6 steam pipes in each chamber, worked from 5 to 35 lb. pressure. Many manufacturers held strong views as to the importance of many of these details, but his experience was that the final working results were the same in each case, notwithstanding all the foregoing differences. If the burnt ore contained the usual 3 per cent. of sulphur, the burner gas 7 to 8 per cent. of sulphur dioxide, combined with reasonable chamber and Gay Lussac space, and a final escape of 1 grain of total acidity, the final results of working are all practically identical, notwithstanding the differences in the construction of the plant enumerated above.

MR. NORMAN HOLDEN said he had to work a set of chambers where they had had to put in the bottom inlets. There was no doubt that the chambers could then be worked with a less capacity of chamber space, but the trouble they had was, that when the fan was stopped occasionally for oiling purposes, they had great difficulty with the burners: that was noticeable immediately the fan was stopped. They were still working the second and third chambers with the tunnels, and they were getting a very great deal more vitriol made, and they were able to catch the plant when it showed signs of going back.

MR. ARTHUR CAREY said it seemed difficult to understand how the initial velocity of the entering gases could be high enough to carry the gases in a fairly straight line the full length of the chamber. In an ordinary vitriol chamber of plant making 150 to 200 tons a week, the gases enter the chamber at some 25 to 30 cubic feet a second; thus they would enter a two-foot square tunnel with an initial velocity of about 7 feet a second, entering a chamber perhaps 100 feet long, with about 400 sq. ft. cross section. Could Mr. Porter give any figures with respect to the comparative speed at which the gases enter, because if the initial velocity of his model was comparatively greater than on one of the large chambers, there must be some considerable modification. For instance, the steam jets entering travelled in the direction of their initial velocity for only a short distance. It would appear that the

initial velocity of those steam jets was considerably greater than the initial velocity of the gases entering the chamber.

Mr. PORTER, in reply, said he had found the water sprays an excellent thing in hot weather, but difficult in cold weather: the chambers got cold during the night and required some little assistance in the way of steam. There was the difficulty of freezing and the filtering of the water: if the jets got blocked instead of getting a spray they would get drops of water, thereby diluting the bottom acid. In reply to Mr. Carey, certain modifications would have to be allowed for in the case of a working chamber, but he did not think that the allowance was quite so great as might appear, because that actual model had been worked with steam and at a temperature in some cases up to 160°. He had made acid in the chamber, so much so that the bottom was actually burnt. Still, the movements of the gases appeared to be quite the same. In practice, where the bottom inlet had been adopted, they had proved that the hottest point was in the centre of the chamber, where the chamber was of reasonable length. Mr. Holden had not found it an advantage when the fan was stopped, but in that case the chambers were very long in proportion to their height and width. There was one large firm that wished to adopt the bottom inlet. They had two No. 1 and one No. 2, and all the other chambers in tandem; they also had several union chambers, mere boxes, the same height, about square. Acting on his advice, they cut out four of these unions and one chamber, and divided the others into two sets, and made more acid than they made before.

With regard to Mr. Carey's question with respect to the increase of 120 tons a week from 65 tons; the capacity had dropped from about 20 cubic ft. per lb. of sulphur to 15, in other cases to 14, 11, 10½, which was the lowest he knew; of course, where this increased work had come about, extra burners had been provided or switched on.

An advantage of keeping the chambers fully up to their work was that, when working a chamber 20 or 30 cubic ft., there was not always sufficient condensation in the back of the chamber to wet the entire surface of the chamber.

In reply to Mr. Arthur Carey, he thought the initial velocity was sufficient to carry the gases the full length of the chamber, but he had no figures from the model before them to give to demonstrate that. He based all his theories and calculations on the questions of temperature; where there was a top inlet taking the gases all along the top of the chamber, there was a very marked decrease at the sides as they come lower down. It appeared from such tests as though there was a straight current of hot gas running from the top of the chamber. It appeared from the temperatures taken at the sides, that the greater heat of the sun at the top and the gases running along the top, caused the gases at the top of the chamber to expand, the atmosphere became rarefied, and it probably deflected the incoming gas at the top, naturally making it work at a slightly lower level, and the hot gas would be lower in the hot weather than in the cold. It was quite simple to find the points at which the gas rose, somewhere about the middle of the chamber; the temperature of the gases coming in was known, and the temperature of the gases going out could be found. The velocity of the gases Mr. Arthur Carey had given at 25 to 30 ft. per second in an ordinary damper flue coming into the chamber, a very high velocity (Mr. Arthur Carey here corrected the velocity as stated by Mr. Porter, dividing the 25 to 30 ft. by the square of the opening into the chamber, and stating that the linear velocity was about 7 feet per second), and when they considered that the surrounding gases in the chamber were to a great extent at rest or dragged at by the incoming gases, that was a very big velocity for a small stream of gases into a big space. The gases hung to the sides of the chamber and the current would bore its way through a considerable distance.

With regard to steam. Whether it was the higher temperature of the steam that made it rise he did not know. That was the observation he had made, and he had carried out a number of experiments at Tennants' Works, with Mr. Hart. They did the experiments in the open air on a still day, and he was surprised at the short distance the steam travelled before it turned upwards; with 30 lb.

pressure, a half-inch nozzle, and the valve a third on, the steam only went 4 or 5 feet before it turned upwards, and the lateral strength of the steam was nothing like what one would suppose it to be. If that was so on a still day, in the open, it would be more so in the dense gases of a vitriol chamber. The conclusion was that the half-inch nozzle was much too coarse. As a rule, steam valves and steam pipes were put on far too large for the work they had to do.

Another most instructive model was one that he had made at Mr. Carpenter's suggestion, admitting the gases at both ends of the chamber, and taking them out at the middle. In that model, the gases worked in precisely the same way as in the one before the meeting, with this difference, that the gases from either inlet met in the middle of the chamber and returned: the fact that the outlet was at the side in the centre of the chamber in no way affected the movement of the gases in the manner shown.

If the gases were admitted at the top precisely the same thing happened as in his first model. They came along the top and met and formed dense banks. He believed that Dr. Hunter had stated that the gases might be taken out anywhere except near where they came in. Mr. Towers had suggested that that was just when the gases should be taken out, and it was quite feasible.

London Section.

Meeting held at Burlington House on Monday, March 1st, 1909.

DR. J. LEWKOWITSCH IN THE CHAIR.

SULPHUR AS A CAUSE OF CORROSION IN STEEL.

BY G. NEVILL HUNTLY.

A considerable amount of work has been published during the last few years dealing with the corrosion of iron and steel, attention having been chiefly concentrated on the effect of the presence or absence of carbon dioxide. An investigation into the cause of pitting in a standby boiler at the generating station of the London Electric Supply Corporation proved that the sulphur in the metal is also a factor that must be taken into account. In these boilers the pitting assumed serious proportions about two years ago, and an increase in the proportion of alkali, caustic soda, in the water proved to be useless in lessening the evil. On examining the boilers numerous blisters were seen, varying in size up to 30 mm. in diameter, the bulk of them being in the neighbourhood of the water level. On pricking the blisters each was found to contain a liquid with a fine black powder in suspension, and a pit was forming in the centre of each blister. As it appeared probable that the examination of this liquid might throw some light on the corrosion, a large number of the blisters were pricked, the fluid collected, and kept from contact with air. This liquid, which was strongly acid to litmus paper, was filtered in an atmosphere of carbon dioxide, and proved to consist of a solution of ferrous sulphate with a slight excess of sulphuric acid, the latter being either free acid or possibly ferric sulphate. The boiler water in which the blisters had been submerged was slightly alkaline, containing 0.635 lb. of caustic soda per 1000 gallons. As the blister fluid available only amounted to 25 grms., its complete analysis was not possible. It contained 2.315 grms. per litre of ferrous sulphate, and within the limits of experimental error practically all the iron was present as ferrous salt. The total sulphate, expressed as sulphuric acid, was 1.92 grms. per litre, the total sulphate in the boiler water being 0.0608 grm. per litre, the ratio of the concentrations in sulphate inside and outside thus being 31.5 to 1.

Assuming that the sodium sulphate was of the same strength inside and outside the blister, the excess of sulphuric acid would still amount to 0.27 grm. per litre.

It is clear that the sulphur could only come from the steel and the oxygen necessary for its oxidation from solution in the boiler water, and it seemed of interest to determine, if possible, how the oxidation takes place. It is well known that the sulphur in steel is present as manganese sulphide, ferrous sulphide only appearing when the quantity of manganese is insufficient. If the sulphide is directly oxidised to sulphate by the oxygen in solution and this precipitated by the alkali in the boiler water, the substance of the blister and the black precipitate in suspension should consist mainly of oxides of manganese. If, on the other hand, the sulphide on oxidation gives rise to free sulphuric acid, the corresponding amount of oxide of manganese remaining attached to the plate, then this acid will act on the whole portion of the metal within the blister, and the precipitate will contain the various constituents of the metal in proportions roughly corresponding to those existing in the boiler plate. This would also be the case if, a little ferrous sulphate once formed, oxidation to ferric sulphate took place at the expense of the incoming oxygen: this ferric sulphate would be reduced by the metal of the plate and the scale would have the same composition as in the attack by free acid.

The analysis of the scale gave the following figures:—Iron, 65.92 per cent.; manganese, 0.28; carbon, 0.50; phosphorus, 0.00; sulphate (SO_4), 3.71; silica, 0.65; calcium, 1.10; moisture, 3.40; oxygen (by diff.), 24.44 per cent. In spite of the precautions taken to exclude oxygen during the washing and drying, it is probable that some oxidation took place, increasing the proportion of ferric oxide. The above analytical figures are consistent with the following composition for the scale:— Mn_3O_4 , 0.39 per cent.; CaSO_4 , 3.74; Fe_3C , 7.56; SiO_2 , 0.65; FeSO_4 , 1.70; Fe_3O_4 , 18.00; Fe_2O_3 , 64.56; water, 3.40 per cent. (The water represents the amount left after drying in a vacuum at the ordinary temperature over phosphorus pentoxide.)

The proportion of manganese does not correspond with what would be expected if manganese sulphate were the first oxidation product, but the figures agree fairly well with the hypothesis of the action of dilute sulphuric acid or ferric sulphate, the products being then precipitated by the alkali of the boiler water. As in a standby boiler the liquid has periods of rest, the oxides deposit on the spot where they are formed, giving a coherent membrane. Under these conditions this acts as a sort of semi-permeable membrane, admitting oxygen but not alkali, thus giving rise to the anomalous effect of an acid corrosion going on inside an alkaline boiler water.

The presence of streaks of sulphide in the steel thus gives a complete chemical explanation of pitting in the case of a standby boiler, and may also serve to explain the corrosion of steel plates along definite lines in experiments in which the liquid has not been kept agitated. It was formerly supposed that provided the sulphur in steel was completely combined as manganese sulphide, the injurious effects on the strength of the steel were minimised. Metallographic evidence has lately been accumulating tending to prove that many fractures follow the lines of manganese sulphide: the facts noted above as to the chemical properties of manganese sulphide form an additional argument for excluding it from steel as far as possible.

It may be of interest to note that the substitution of an alkaline arsenite for caustic soda in these boilers completely stopped the trouble, no blisters having developed during the last two years, an effect possibly due to the oxidation of the arsenite by the dissolved oxygen.

DISCUSSION.

Mr. W. THOMSON asked if the skin formed over these blisters was magnetic oxide of iron. He thought it possible that peroxide might first form and the sulphur in the iron might be converted into sulphuric acid at the expense of the existing peroxide producing magnetic oxide, which was usually found in boilers, the sulphuric acid combining to form ferrous sulphate, leaving a skin of the magnetic oxide over the blistered part.

Mr. GRANT HOOPEE asked whether the author investigated the composition of the material actually forming the skin; and to what he attributed the formation of such a blister. It seemed to him to suggest the production of gas at that point.

Mr. W. C. HANCOCK understood the author to say that the addition of alkali to the water did not cause pitting; but at some works with which he was connected a water softening plant was installed; the first time the boilers were examined a considerable amount of pitting was found in places. This was attributed to the water softening plant, and it was found that after that plant was more systematically worked, with less excess of alkali, the pitting practically disappeared.

Mr. W. McD. MACKEY said that tannin materials seemed to have a good action in taking up the oxygen and preventing this pitting.

Mr. HUNTLY, in reply, said it was not possible to separate the substance of the blister from the suspended precipitate inside: the latter was relatively small in amount and probably had the same composition as the substance of the blister itself. Although every care was taken to keep the scale as far as possible out of contact with air (filtration in carbon dioxide and drying over phosphorus pentoxide in a mercury pump vacuum), it was probable that a certain amount of oxidation took place. Hence the original percentage of the oxide, Fe_3O_4 , might have been higher than that given in the paper, with a corresponding reduction in the amount of ferric oxide.

CELLULOSE AS A POLYSACCHARIDE: A BRIEF REVIEW OF OUR PRESENT KNOWLEDGE.

BY J. F. BRIGGS.

One of the first facts which a student of chemistry learns about cellulose is that, like starch, it belongs to the group of polysaccharides and that its constituent monose groups are composed mainly if not entirely of dextrose. This view was founded on experiments made as early as 1819 by Braconnot and elaborated subsequently by various observers, chiefly Flechsig, 1883, and Stern, 1895. It has received support by a large number of attempts made on an industrial scale to produce alcohol from cellulose or from its raw material—wood. It likewise appears justified *a priori* from the manner of the formation of cellulose in the plant from sugar, so far as this has been investigated, and further by analogy with the most typical and fully studied of the polysaccharides—starch. Thus the poly-dextrose nature of cellulose may be taken to be self-evident and perhaps there has been a tendency to accept it too much without question. A critical revision of the literature of the subject, however, shows that the amount of reliable evidence is extremely scanty, and that much of it is of a contradictory nature. So far as the reactions of the aggregate are concerned the properties of the two substances, starch and cellulose, are very similar. Both give a series of analogous esters, corresponding to the presence of 3 free hydroxyl groups, both possess the slightly acid functions towards alkaline bases characteristic of all the saccharides, and both are susceptible to a degradation of the aggregate under the hydrolytic action of acids. But when the manner of the hydrolytic degradation is studied we are struck by profound differences, which can only be accounted for by differences in the mode of association of the C_6 groups constituting the aggregates. A vast amount of work has been devoted to the dissection of the starch complex, with the result that the constitution of this substance as a complete poly-dextrose has been established beyond dispute. The enzyme diastase has been one of the most important instruments in this dissection, but unfortunately cellulose has resisted the hydrolytic influence of every enzyme hitherto brought to bear on it. We are obliged therefore to fall back on the more drastic action of hydrolysing acids, complicated as this is by collateral phenomena of esterification, internal structural transpositions, reverse condensation, humification, etc.

The first point we note then is that whereas starch is converted readily and almost completely into dextrose by digestion for 3—4 hours at 100° C. with 2 per cent. sulphuric acid, cellulose under the same conditions is structurally disintegrated, it is true, but yields only traces of soluble sugars. The ease with which hydro-cellulose is produced and the great resistance of the product to further hydrolysis, suggests the hypothesis that the cellulose aggregate contains at least two hydro-cellulose complexes united together by an ordinary anhydride linkage of the starch type, but that the condensed linkages of hydrocellulose itself are of a totally different order. By digestion with dilute acids at very high temperatures larger but variable amounts of sugars are produced, but it is extremely doubtful whether the saccharification of cellulose has ever been carried as far as 50 per cent.

The most complete study of the direct saccharification of cellulose is contained in a series of papers by Simonsen (*Zeits. angew. Chem.*, 1898, 195, 219, 962, 1007). He worked only on wood cellulose with the industrial objective of the manufacture of alcohol. He found the most favourable conditions for the saccharification of 40 grms. of cellulose to be a digestion for 2 hours at 6—8 atmospheres with 1680 c.c. of 0.5 per cent. sulphuric acid; longer digestion caused a serious destruction of sugar. From the best of his experiments (an exceptional case) he claims to have obtained 45 per cent. of sugar and 44 per cent. of residue. On treating the residue again in the same way it yielded 27 per cent. of sugar, but he does not appear to have followed up the series by a third treatment. Simonsen's results, which are admitted to be the most reliable, have recently been criticised by Körner (*Zeits. angew. Chem.*, 1908, 2353), who repeated some of his experiments. Körner points out that Simonsen's yields of sugar were determined only by the cupric reducing power of the extracts and that this is not always a legitimate measure. Simonsen's extracts were not completely fermentable, and it is doubtful whether the whole of the cupric reducing power could be credited as sugar, certainly not as dextrose. Körner, working on Simonsen's lines, obtained a yield of 12.8 per cent. of alcohol from wood cellulose, corresponding to, say, 26 per cent. of dextrose. From "hydro-cellulose" he obtained 18 per cent. of alcohol, but he does not indicate whether the hydrocellulose was prepared from wood or cotton cellulose. Both Simonsen and Körner limited their investigations by strictly utilitarian industrial conditions and their work consequently lacks the scientific value of a contribution to the theory of the constitution of the cellulose aggregate. Nevertheless, Körner concludes with the following remark:—"The yield of alcohol theoretically possible from 100 grms. of dry cellulose is 56.9 grms., but even in the most favourable cases, not more than 25 per cent. of the theoretical quantity was obtained by the simple hydrolysis of the cellulose. It is therefore conceivable that of the whole cellulose complex, $(C_6H_{10}O_5)_x$, only a portion is capable of hydrolysis and conversion into fermentable sugar."

Körner's work, however, hardly warrants such a conclusion, since being limited to industrial conditions, he made no study of the susceptibility of the residues from the first digestion to further hydrolysis with fresh acid.

Whilst the credit and debit account as between cellulose and dextrose by direct hydrolysis is unsatisfactory, the results shown for the hydrolysis of cellulose indirectly by way of its esters are no more complete.

Braconnot and his successors proceeded by employing sulphuric acid of such a strength that its first action in the cold is one of solution and esterification (see Stern, *Chem. Soc. Trans.*, 1895, 74). In this way the acid sulphuric esters of a series of dextrin-like bodies are obtained which on long boiling in presence of dilute sulphuric acid are gradually hydrolysed into dextrose. Stern has carefully fractionated these sulphuric esters, determining the cupric reducing power and the specific rotatory power for each fraction, and the series has a general aspect very analogous to that of a maltodextrin series of starch products. The gradual production of sugar on continued hydrolysis is accompanied by the splitting off of sulphuric acid from the ester. Neither Stern nor previous workers appear to have actually obtained any but quite insignificant

quantities of dextrose (say, 5 per cent.). Stern's "cellulose sulphuric acids" are non-reducing bodies, but his hydrolytic series are made up of potential dextrose groups. It is however to be carefully noted that the yields of soluble barium cellulose sulphates from which all Stern's deductions were made never accounted for more than 48 per cent. of the original cotton cellulose taken. Other chemists have examined other celluloses than cotton on similar lines; thus Lindsay and Tollens isolated 3.5 per cent. of crystalline dextrose from wood cellulose by this method. Ernest (this J., 1906, 388) obtained about 4 per cent. of a dextrose syrup from ramie cellulose in the same way.

A third line of attack was initiated in 1901 by Skraup (*Monatsh.*, 22, 1011). This chemist also dissected the cellulose by way of its esters, and by the action of acetyl chloride he obtained about 26 per cent. of the chlor-acetate of a biase sugar corresponding, say, to about 15 per cent. of the sugar itself. This sugar, cellobiose, is hydrolysed by boiling dilute sulphuric acid to dextrose.

So far as I can make out, observations of the above order constitute the chief evidence on which the poly-dextrose character of cellulose has been based, and the obvious criticism of this evidence is that at the best not more than one-half of the cellulose has been accounted for.

Hence there is a wide field of systematic research open for the complete determination of the position of cellulose in the group of polysaccharides. The number of possible methods of hydrolysis is by no means exhausted, and conditions must be found whereby the tendency to reverse reactions is restricted. In the case of the dissolved sulphuric acid esters of cellulose this restriction might be effected by carrying out the subsequent hydrolysis over long periods at the ordinary temperature instead of by boiling. In addition to sulphuric acid there is another acid, viz., syrupy phosphoric acid, which dissolves cellulose, so far as we know without esterification, the hydrolytic action of which has not been studied. It is interesting to note in this connection that whereas syrupy orthophosphoric acid dissolves cellulose completely, the glacial meta acid is entirely without action at the ordinary temperature.* Researches on the direct hydrolysis of cellulose by dilute acids should be carried out by repeated treatments for short periods in the autoclave, with frequent removal of the hydrolysed products from the sphere of action and full investigation of the resistant residues until the whole of the original cellulose has been converted. Skraup's line of research on the hydrolysis of the acetic esters of cellulose is capable of considerable development and extension since he has adopted the principle of cold hydrolysis extended over long periods of time. In all cases the possible lability of the constituent units of the aggregate must be taken into account and the influence of preliminary or simultaneous treatments likely to cause intramolecular transpositions should be studied.

When a method of total hydrolysis has been worked out in the case of the normal cotton cellulose, it should be extended to ascertain the possible changes of internal structure brought about by such treatments as mercerisation, oxidation, etc. Next it would have to be applied to the less homogeneous industrial forms of cellulose obtained from wood or grasses. It is known that these celluloses contain, either constitutionally or in the form of residual impurities from tissues other than the fibre walls, polysaccharides which yield monoses other than dextrose, e.g., pentosans and mannosans. These celluloses would have to be examined before and after fractionation by specific treatments, e.g., extraction with concentrated solutions of alkali hydroxides. Finally, the questions which remain to be answered are: Is cellulose a true and complete polysaccharide like starch? Can 100 parts of cellulose be accounted for in terms of 110 parts of dextrose? If not, what is the nature of the residue? Lastly, is the pure fibrous cellulose of wood constitutionally identical with the normal type of cellulose as we know it in the cotton fibre?

* In a recent paper by Hengoumeneg and Morel (*J. Pharm. Chim.*, 1908, 28, 486) the merits of hydrofluoric acid for effecting complete hydrolysis of proteins, without secondary reactions, are discussed; this acid might also be tried on cellulose.

New York Section.

Meeting held at the Chemists' Club on Friday, January 22nd, 1909.

MR. MAXIMILIAN TOCH IN THE CHAIR.

PRESENTATION OF THE PERKIN MEDAL.

The CHAIRMAN referred to the absence through illness in his family of Dr. Behr, the recipient of the Perkin Medal. After some remarks on the origin of the medal and the useful work of Dr. Behr,

Professor C. F. CHANDLER (Past-President), in presenting the medal to Dr. Nichols, on behalf of Dr. Behr, said:—"It is with deep regret that we are unable to have the pleasure this evening of the presence of Dr. Arno Behr, the distinguished chemist who has been selected by the representatives of our different chemical societies as most worthy of the honour of receiving the third issue of the Perkin medal. This honour could not have fallen upon a more worthy representative of successful effort in the application of chemical science to the industrial arts.

Dr. Behr came to this country in 1878, on the invitation of Mr. Matthiessen, of the firm of Matthiessen and Wiechers, and was engaged in chemical work in their sugar refinery in Jersey City. His first work, however, was largely of an experimental nature. Great interest was then shown in the manufacture of glucose directly from corn, a number of patents, having relation to such processes, being published at that time. The object was to cheapen and simplify the process by working on the whole corn, instead of first separating the starch. This would, of course, have decreased the cost of manufacture and would have increased the yield considerably. Mr. H. C. Humphrey originated the idea, and it was decided to carry out an experiment on a manufacturing scale. An old sugar refinery in New York was rented for that purpose. While watching this work, it occurred to Dr. Behr that a great deal of fat might be found concentrated in the residue. Actual tests confirmed this observation and led to the application for a patent, which was issued to Messrs. Humphrey and Behr, under date of September 30th, 1879 (U.S. Pat. 220,116), the title being: "A Process for extracting oil from the residuum in the manufacture of glucose." However, the process was never carried out, because it was found impracticable to convert the corn direct into glucose.

In 1880 Mr. E. A. Matthiessen, while travelling in Europe, saw a new process of making starch from corn in operation at Cervignano, near Trieste. The inventor was Professor Chiozza. Corn was steeped for one or two weeks in cold dilute sulphurous acid, cracked between rollers, and the magma brushed in revolving metallic sieves with the addition of water until the starch was all removed from the hulls, only hulls and germs remaining upon the sieve. These were dried and separated in a fanning mill. The starch was deposited on tables and separated from the gluten without the use of alkali. The process contained features far in advance of that practised in the United States, which induced Mr. Matthiessen to acquire the American patent. But it soon became evident that this process, which was carried out at Cervignano in a factory, the output of which did not exceed 200 bushels of corn, could not be applied in an American factory built for a daily capacity of 10,000 bushels, for this was the size of the factory agreed upon for the manufacture of glucose and grape sugar. Therefore, it became the task of Dr. Behr to modify and adapt the process to the conditions imposed by a large production. Dr. Behr tried to replace the action of Chiozza's brushes by beating the crushed corn with knives revolving at a high speed and set in a trough on a horizontal shaft. He did not fully succeed in his main object of loosening all of the starch, but after diluting the magma with water, he made the far-reaching discovery that by gently stirring, a layer of germs was formed, which floated on the surface of the liquid. This observation led to the introduction of one of the most important operations in a glucose and starch factory—the separation of the oil-bearing germ—

and furnishes a striking example of the applicability of laboratory experiments to large industrial processes. Dr. Behr secured a patent covering the process of separating the germs from the rest of the corn, which was obtained on September 30th, 1881 (U.S. Pats. 247,152 and 247,153). To test the process commercially an experimental factory was erected at the sugar refinery in Jersey City, and there several important details were worked out. One of the problems was the disposal of the gluten. This task was solved by converting it into a dry fodder, which, ever since its introduction, has occupied the foremost position among the concentrated animal feeding stuffs.

At this time crystallised, anhydrous grape sugar was being obtained by a patented process, originated by Professor Soxhlet. It was obtained by crystallisation from a methyl-alcohol solution and was a very beautiful product. Dr. Behr had been experimenting at that time with a view of obtaining such crystallised dextrose, but all his efforts were futile until he resorted to inducing crystallisation in the mother liquor by introducing crystals of anhydrous dextrose. He eventually worked out a method of crystallisation, by which the crystal was formed in such a way that the remaining mother liquor could readily be drained off. The sugar thus produced takes first rank among all the corn products, and the process is remarkable in that it enables the manufacturer to turn out commercially, in large quantities, a dextrose which is practically chemically pure. This important discovery of Dr. Behr's—the method for refining grape sugar without the use of alcohol—is secured by U.S. Patents 250,333 and 250,334, of December 6th, 1881; 256,622 and 256,623, of April 18th, 1882, and 259,794, of June 20th, 1882. A paper on the subject was published in the "Berichte der deutschen chemischen Gesellschaft" in 1882, as well as in the "Journal of the American Chemical Society" during the same year. In the meantime, a Company had been formed and the erection of a factory in Chicago had been started for the exploitation of the Chiozza-Behr process: the original intention was to manufacture glucose and the ordinary kinds of grape sugar, but the new crystallised, anhydrous grape sugar appeared so attractive that the factory was arranged for the sole manufacture of this product. This enterprise, however, proved unprofitable, as there was no market for such large quantities of the new sugar. After running from November, 1882, to February, 1883, never with more than one-seventh of its capacity, and more or less in an experimental way, the factory was closed in the spring of 1883, and Dr. Behr thereupon returned to Jersey City and resumed his duties with the Matthiessen and Wiechers Sugar Refining Co.

The Chicago factory, however, during the short time of its running, had demonstrated the practicability of the new processes, and the directors decided to operate it again, after providing a new installation for the manufacture of glucose, in addition to that of ordinary grape sugar and the anhydrous sugar. It was started in August, 1883, Dr. Behr being in charge as superintendent. At first only anhydrous sugar and its by-products (the latter also inventions of Dr. Behr) were manufactured; the former found a market with the wine-makers and the latter with the brewers. In January, 1884, the additional equipment for the manufacture of glucose was completed, and then came a strenuous time of work and competition with existing glucose factories, during which only the large profit made on the anhydrous sugar saved the Company from insolvency, as the manufacture of glucose and ordinary grape sugar had not as yet been worked out to such a degree as to make it remunerative. Dr. Behr gradually increased the grind from 2900 bushels per day in 1885 to 10,000 bushels in 1890. From the start the aim was to produce as many specialities as possible. With that end in view, Dr. Behr introduced the manufacture of mill starch, dextrin, British gum, caramel, so-called high converted sugar, climax sugar, and other products, which, although started in a small way, were in most cases brought up to a considerable output. There was, of course, keen competition in starch, dextrin, and British gum, but Dr. Behr succeeded in working out new and cheaper methods of manufacture, which enabled him to keep ahead of competition. During this time he also worked out a valuable method for manufacturing con-

fectioners' glucose, which is protected by U.S. Pat. 406,599, July 9, 1889.

In 1889 it was at last decided to commence the manufacture of corn oil, and the Behr method of separating the germs was thus put into actual operation. The production of corn oil has since then assumed large proportions, and the oil itself is to-day the highest priced product obtained from corn. The output of oil in the glucose and starch factories in this country approaches almost 200,000 lb. per day. In March, 1890, an explosion took place, which destroyed the starch and dextrin plants of the Chicago factory. The explosion was caused by the ignition of powdered starch in the dextrin department. Dr. Behr responded to a call for assistance, and while attempting to put out the fire, the explosion occurred and he was severely injured. Upon his recovery, a year later, he retired from the active management of the works and devoted himself exclusively to scientific research.

In 1893 Dr. Behr secured U.S. Pat. 491,234, for the recovery of the ingredients extracted from the corn during the steeping process. Thus, another valuable by-product was obtained, the monetary returns from which exceeded all expectations.

During the years following Dr. Behr worked out two interesting products, one a vulcanised corn oil, which, although not one of the large articles of manufacture, has nevertheless found considerable favour with the trade, and is manufactured quite extensively. The other product was a so-called "thin boiling starch," which is used especially by the confectioners in high-grade work. Besides these, there are various inventions and improvements discovered and worked out by Dr. Behr, which are not protected by United States patents.

After first developing the manufacture of the bulk products—glucose, grape sugar, and mill starch—Dr. Behr made their manufacture lucrative by his remarkable exploitation of the by-products. To him, more than anyone, the American industry of corn products owes an everlasting debt of gratitude.

It is a great satisfaction to all those who took part in founding the Perkin Medal that we are able to find as recipients of this medal such worthy followers and disciples of Dr. Perkin as Mr. Herreshoff and Dr. Arno Behr.

I take pleasure in placing in your hands, Dr. Nichols, as representing Dr. Behr, this beautiful Perkin Medal as a token of the appreciation in which he is held by the chemists of the United States.

Dr. NICHOLS (Past-President) said: Since the foundation of the Perkin Medal it has been my fortune to assume various attitudes in relation to it. I had the honour of presenting the first Perkin Medal to Sir William himself on the memorable occasion of his visit to the United States in 1906. The following year it was my privilege to participate in the presentation of the medal to my old friend and associate, Mr. J. B. F. Herreshoff.

In Dr. Behr's behalf I accept the medal for him, with a full realisation of the great honour which has been conferred, and with the hope that the encouragement which others will get in the future will be heightened by the knowledge that if what they are doing at the present time does not meet with immediate recognition, they can depend upon the chemical fraternity to see that in the case of really good work, time will be a benefit to them rather than a detriment. The fact that Dr. Behr has been away from us so long and at such a great distance, and yet has seen his work of years ago recognised, speaks volumes for the character of the profession which has to pass from year to year on the names presented for the Perkin Medal.

In his name I thank you most heartily for the honour.

THE AMERICAN INDUSTRY OF CORN PRODUCTS.

BY T. B. WAGNER.

The award of the Perkin Medal is an occasion of great moment to every chemist. This year the honour has fallen upon my friend, Dr. Arno Behr, whose life-work is identified with the development of the industry of corn products. It seems fitting, therefore, that on this occasion some account should be given of this great and typically

American industry. This task has been allotted to me, and I look upon it not only with keen pleasure, but as a great privilege.

Although corn is the principal cereal raised in the United States—"Corn is King"—comparatively little is known about its use in industry, to say nothing of its sowing and growing, harvesting and shipping, among people who live removed from the great corn belt of our Central and Western States.

Indian corn, or maize, is undoubtedly native to America, although for a long time it was claimed to be of Asiatic origin. But as this corn was not known in the old world until after it was found in the new, there can be hardly any doubt as to its original habitat.

At the time of the discovery of the new continent, Indian corn was one of the staples of agriculture from the La Plata Valley northward to the United States. It has names in all the languages. The natives planted it around their temporary dwellings where they did not form a fixed population. Indian corn was found as a common food when Europeans first landed in New York. Extensive fields of this grain were cultivated and the grain preserved for food. When, in 1535, Cartier visited Hochelaga, now Montreal, that town was situated in the midst of extensive cornfields. In 1620 the Pilgrims found extensive plantings near Plymouth, Massachusetts; and Columbus found it on the West India Islands about the end of the fifteenth century. The burial mounds of the natives of North America, who preceded those of our day, the tombs of the Incas, the catacombs of Peru, contain ears or grains of corn, just as the monuments of ancient Egypt contain grains of barley and wheat and millet seed. In Mexico, a goddess, who bore a name derived from that maize, answered to the Ceres of the Greeks.

The Smithsonian Institute at Washington has an ear of corn found deposited in an earthen vessel 11 feet under ground in a grave with a mummy in Peru.

Whether the true origin of Indian corn will ever be ascertained is doubtful, but so much is certain, that the white settlers of America early learned from the native Indians the use of corn as an article of food. Several Indian names for certain preparations, such as samp, hominy, succotash, have passed into the language of the American people.

Indian corn belongs to the gramineæ or grass family. Botanically, it is known as "*Zea Mays*," and is separated into six general groups, representing different species. These groups are as follows:—

1. *Zea tunicata*, the pod corns.
2. " *evecta*, the pop corns.
3. " *indurata*, the flint corns.
4. " *indentata*, the dent corns.
5. " *amylacea*, the soft corns.
6. " *saccharata*, the sweet corns.

The division, which is of supreme importance commercially, is that of the dent corn, *Zea indentata*.

Corn is the most valuable crop grown on American soil. In quantity and value it is greater than all the other cereal crops; in fact, it is this year nearly as large as the great crops of cotton, hay, and wheat combined, thus bearing out the prophecy of our illustrious statesman, James G. Blaine: "Corn will yet be the spinal column of the nation's agriculture."

In 1838 the corn raised in this country amounted to 377,531,875 bushels, whereas in 1908—seventy years later—the crop had increased to 2,643,000,000, or seven times that of 1838. The great importance of the crop may be better realised when it is stated that a fluctuation of a single cent in the bushel price of corn means a fluctuation in money value to the farmer of 26 million dollars. The value of this year's crop almost surpasses belief. It is \$1,615,000,000. This wealth, that is grown out of the soil in four months of rain and sunshine and some drought too, is enough to cancel the interest-bearing debt of the United States, and to pay for the Panama Canal and 50 battleships.

At the Paris Exposition, the United States exhibited 108 separate and distinct commercial products made from corn. It enters into the manufacture and composition of products in as wide a range as from rubber-shoes to our daily bread; from chewing gum to dynamite; from

bon-bons to battleships. In this day of commercial economy no particle of the corn plant is permitted to go to waste; the grain, the cobs, the husks, and the stalks all are utilized. Seven States of the Union—Illinois, Iowa, Kansas, Nebraska, Missouri, Indiana, and Ohio—comprise the territory familiarly known as the "Corn Belt." Illinois leads all the other States in the yield per acre, as well as the amount of acreage and production, the latter amounting approximately to one-fifth of the entire crop of the United States.

Of the total crop, however, only about 10 per cent. is consumed by the industries and employed in the export trade. Of this, the industry with which I am connected consumes approximately one-fifth or 50 million bushels per year, where two-fifths are required by the fermentation and milling industries, and an equal amount finds its way into the export trade of this country.

The corn plant is very pliable in the hands of skilful breeders. Cyril G. Hopkins has succeeded, through ten generations of breeding at the University of Illinois, in increasing the average protein from 10.92 per cent. to 14.26 per cent., and, on the other hand, in decreasing it to 8.64 per cent.; in the same way, the average percentage of oil has been increased from 4.70 per cent. to 7.37 per cent., and diminished to 2.66 per cent.

First, the farmer carefully selects the seed corn most suitable for his particular conditions and requirements. In the month of April the ground is ploughed, and then harrowed and re-harrowed until the soil is thoroughly pulverised. The proper time for the planting of corn is from the 1st to the 10th of May, but it can be planted to good advantage any time during the month of May, and even later if the season is favourable. The old-time method of planting by hand has been discarded in favour of automatic planting machinery. The prime object sought by the use of the corn planter is to get corn planted in the field in hills and a uniform number of kernels in each hill. It takes about ten days for the plant to show itself above ground, at which time the "cultivating" is immediately begun. The objects of cultivation are, first, to destroy weeds; second, conserve soil moisture, and, third, to aerate the soil. It is gone over with the cultivators usually three times, and is then, as it is called, "laid by." By this time the stalk is sufficiently high to shadow the ground to some extent and the weeds cannot get a start. The plant then grows without further attention. The great bulk of the corn crop requires four months to mature, although there is an early variety of corn, called a "ninety-day corn." The corn usually reaches a height of eight to ten feet, but a height of fifteen feet is not unusual.

After it is thoroughly matured, and if the corn is wanted for fodder, it is cut and preserved in shocks until it is needed for food. The rule, however, is to let the corn remain in the field and then to husk the ears from the standing stalks, which latter are allowed to remain in the field until spring, when they are broken, raked, and burned. In the Corn Belt States, however, the corn is harvested with binding machines, which cut and bind the corn;

these bundles are stacked together and then form the corn "shocks."

The latest in corn harvesting machinery is the corn harvester and sheller. It consists of a corn binder, in which the binding apparatus is replaced with a platform and windlass. The corn is cut but not bound. It collects on the platform until a shock of the desired size is secured. The machine is then stopped, the shock tied by hand, the windlass ropes adjusted and the shock deposited on the ground in an upright position. Where formerly the farmer was obliged to go through the fields and husk each ear separately, he now calls into service husking machinery. These machines, which are usually portable and are often employed on the co-operative plan, separate the ears from the stalks more neatly than any "hired" man could or would do.

The corn is now ready for the market. The farmer hauls it to the elevators, where it is "shelled" by machinery; in a great many sections it is shelled in the country by a portable sheller, and then delivered to the elevators. Here it is put aboard the cars and sent to market centres, and finally arrives at the factory, where the chemist takes the kernel in hand and from him we obtain this cross-section in which:

(a) Represents the husk, or skin, which covers the whole kernel; it consists of two distinct layers, the outer and inner, which, when removed, constitute the bran and contain practically all the crude fibre of the whole grain.

(b) A layer of gluten cells, which lie immediately underneath the husk; it is yellow in colour, and cannot be readily separated from the remainder of the kernel. This part is the richest of any in gluten.

(c) The germ, which is readily distinguished by its position and form; it also contains gluten, though it is particularly rich in oil and mineral constituents.

(d) The endosperm, which is composed chiefly of starch; the dark colour indicates the yellow, flinty part, in which the starch-holding cells are more closely compacted.

These different parts have the following chemical composition:—

	Proportion of parts.	Ash.	Protein.	Fibre.	Nitrogen free Extract.	Fat.
Original kernel ...	100.0	1.7	12.6	2.0	79.4	4.3
Skin	5.5	1.3	6.6	16.4	74.1	1.6
Germ	19.2	11.1	21.7	2.9	34.7	29.6
Starchy and hard parts	84.3	0.7	12.2	0.6	85.0	1.5

The corn goes now through a maze of bewildering operations and manipulations, necessary to obtain the various products in the final state of perfection and purity, in which they reach the consumer. The corn bought by us is graded at the Corn Exchange and is almost exclusively of the +2 and +3 grades. To remove impurities, stone, dirt, dust, &c., the grain is passed through cleaning and separating machinery and the purified corn is then delivered to the corn bins and thence to the steeping tanks, wherein it is soaked in warm water, into which a slight amount of sulphur dioxide has been introduced. The steeping causes the corn to swell, brings about a softening of the grain, and facilitates the subsequent separation of the germ, which is effected after it has passed through a preliminary grinding, whereby the corn is split or cracked. This is done by attrition mills, usually the "Foss" mills. This mass is then conveyed to the so-called "separators," huge cast iron vats of semi-cylindrical shape, and in these the separation of the germ is effected with almost mathematical precision, the operation being at once an extremely simple and clever one. It is one of the early inventions of Dr. Behr, and has perhaps done more than any other invention towards making the glucose industry commercially possible, as it led to the production of corn oil, of all the ingredients of corn the one yielding the highest price. The process is based upon the observation of Dr. Behr, that the germs, which contain a large amount of oil, readily rise to the surface, when suspended in the mass of ground corn and starch milk. This is due, of course,

to the difference in specific gravity. The process is a continuous one, the ground mass being introduced at one end of the apparatus, while the germs are discharged at the top, and the ground corn plus the starch milk at the bottom of the opposite end. The germs, thus liberated, are repeatedly washed to remove any adhering starch; they are then delivered to the germ drying plant, where they are passed through revolving steam dryers and are then conveyed to the oil plant.

In the latter, the usual practice is followed of expressing the oil by hydraulic means, the same as in cotton-seed and linseed oil works, the resultant products being corn oil and a residue—corn oil cake, which belongs to the same class of animal feeding stuffs as cotton and linseed cake, but exceeds them in nutritive value, because of its digestibility. In a medium-sized glucose factory, the production of corn oil approximates 100 barrels a day, requiring about 25,000 bushels of corn. A bushel of corn contains about 80,000 kernels of corn and each kernel contains one germ; therefore 2,000,000,000 kernels of corn, or 2,000,000,000 germs are required, and must be handled to yield that output. Dr. Behr's invention permits this important step to be made with almost mathematical precision.

Corn oil is a very interesting product. Its ordinary uses are found in the manufacture of soaps, soap powders, in the tanning industry, in paints, etc., the bulk of the product being exported to Europe.

In corn oil we have the raw material for an auxiliary of natural rubber. When vulcanised, it forms an admirable material to be used with rubber in the manufacture of rubber-bands, rubber-boots, surgical instruments, tyres for automobiles and bicycles, oil cloths, rain-proof cloth, insulating wires, artificial sponges, and a great number of other products. This article, too, is a product of Dr. Behr's fertile mind.

More recently, we have succeeded in splitting corn oil into glycerin and fatty acids. The latter furnish the soap-makers with a superior stock at a lower cost; lower, considering the yield and the fact that for saponifying, soda-ash may be used in place of caustic soda; the glycerin enters chiefly into industrial use.

We have seen the germ removed from the ground corn, the latter now consisting of the bran, the gluten, and the starch itself. This mass is now ground fine, in so-called Buhr mills, the coarser part or bran being separated by running the mass over silk sieves, which move back and forth at a high rate of speed. The starch milk runs through the silk sieves, which in the factory are termed "shakers," and is collected in tanks for that particular purpose. Like the germ, the bran is removed from the shakers, washed, dried, and ground, and is put on the market in this form as a cattle food, the protein contents of which average about 14 per cent. The starch milk, containing the gluten, is now run over slightly inclined troughs called "starch tables," upon which, by a process of settlement, the starch is built up in a solid layer, whereas the lighter ingredients—gluten, fibre, etc.—are carried off in a current of water over the end of the starch tables. This gluten is concentrated, filter-pressed, and dried in the same fashion as the bran, and put on the market as gluten meal, the protein contents averaging over 40 per cent. It is now quite the practice to unite the two, that is, the bran and gluten, when still in a wet state and send the mass through the filter presses; then the concentrated liquid obtained from the steeping of the corn is added, and the moisture of the whole reduced in revolving steam dryers to approximately ten per cent. It is then ground fine, sacked, and put on the market as "gluten food," having the following average composition:—

	Per cent.
Water	10.36
Protein	25.95
Fat	2.18
Starch	18.09
Fibre	6.50
Ash	3.70
Nitrogen-free substances	33.22

The soluble substances in "gluten food" approximate 15.50 per cent.; the nitrogen-free substance contains 17—18 per cent. of pentosans.

The "gluten food" thus obtained varies in composition in proportion to the efficiency factor prevailing in the individual works; for instance, in a well-equipped and well-regulated factory, the amount of protein will usually run at 26 per cent., whereas in factories conducted less efficiently, the amount of protein may not exceed 18 per cent. The amount of starch in the feed will vary correspondingly.

Among the concentrated feeding-stuffs found on the American market, gluten food is conceded the first place, not only because of the high percentage of nutritive materials contained therein, but because of its palatability and its remarkable digestibility.

I have referred to the water in which the corn is steeped; it contains the most valuable ingredients of the corn. During the steeping, by far the largest amount of the mineral constituents, as well as the soluble organic matter, are leached out. These consist of the organic phosphorus compounds, albuminoids, sugar and other carbohydrates, potassium salts, etc. They are hygroscopic and frustrate all efforts to recover them in dry form. Recognising the great value of these materials, Dr. Behr devised ways and means of recovering them, which are described in U.S. Patent 491,234, issued February 7, 1893. Briefly explained, Dr. Behr recovered these constituents of the corn by evaporating the steep-water to a thick syrup, which contains these substances, partly in solution and partly in suspension. On a dry basis, the steep-water has the following composition:—

	Per cent.
Crude protein	38—43
Reducing sugars as dextrose	25—30
Phosphorus as P_2O_5	6—8
Potash	5—6
Magnesia	2—3

This syrup is added to the wet gluten feed and the mixture is then dried.

It is customary to place the products just described, that is, the oil, the oil cake, the bran, the gluten meal, and the gluten feed, in a group by themselves under the generic term, "by-products." However, the manufacture of these products, has, within the last ten years, undergone such remarkable and marvellous evolutions, that to-day the term "by-products" is hardly justified. These products form as integral a part of our manufacture as the bulk products—corn, syrup, and starch, and their preparation necessarily receives the same degree of watchfulness and care.

Let us now return to the principal part of the corn—the starch. We saw it on the "tables," practically free from the hull, the germ, and the gluten. In this condition it is called in the factory "green starch," and forms the raw material for the manufacture of corn syrup and corn sugars, for mill, laundry, and edible starch. Up to the time when the manufacturers of corn syrup entered upon the manufacture of mill starch, the textile trade depended for its requirements almost entirely upon potato starch, imported from European countries. The small starch factories located in this country contributed but a small share of the demand. The corn syrup manufacturer, because of his large grind, was able to produce commercial mill starch at such a low figure as to replace to a very large degree the European product. Again Dr. Behr, with keen foresight, was the first to commence the manufacture of this article, which has since grown into one of our most important products, some factories turning out as much as 500,000 pounds per day, most of which, either in "pearl" or powdered form, is consumed in cotton and other textile industries for stiffening or finishing the fabrics, and in the manufacture of paper; it is also used for sizings, pastes, and gums.

The "green" starch is removed from the "tables" and diluted with water until it forms a thin starch milk, which, in the case of corn starch, is refined very carefully by a number of well-regulated operations. It is then deprived of the bulk of water and the starch, containing now between 40 and 50 per cent. of water, is introduced into drying kilns of various descriptions, wherein it remains until the moisture is reduced to 10 per cent. It is then ground fine, run through revolving silk screens, and put up either in package form for home consumption, or in barrels and bags for the trade.

The oldest corn starch made for table use is Kingsford's, produced at Oswego, N.Y.

Up to the year 1842 wheat starch was the only starch produced in this country; about that time Thomas Kingsford, while superintending the wheat starch factories of William Colgate & Company, in Jersey City, N.J., conceived the idea that in Indian corn lay the source of an abundant starch supply. Experiments made on a small scale proved the feasibility of his project, yet all attempts to interest capital and the producers of wheat starch to manufacture this new starch resulted in failure. They were making money, and why should they not continue manufacturing starch from wheat instead of taking up a wild project? His idea continued to be ridiculed as impracticable and visionary; however, after numerous and tedious experiments, he was able to produce in 1842 his first marketable starch. Since then, this industry has seen a wonderful rise, and to-day everybody is familiar with the "corn starch" for table use, which has grown in popularity until it is now one of the best known staple food products.

When laundry starch is desired, the operations and chemical treatment are modified somewhat. There are a number of other commercial grades of starch—as, for instance, food and baking powder starch and thin boiling starch. The manufacture of the latter, also a production of Dr. Behr, has grown from what might be called a laboratory scale to a large commercial commodity, the principal consumers being the confectioners.

From the powdered starch, the dextrins are made by a process of "calcining," a number of grades being produced, verging in colour from a pure white to a dark yellow, such as white, canary and dark dextrins, British gums, etc. Some of the dextrins are made by injecting a spray of diluted nitric acid into the powdered starch. Most of the dextrins are used by the textile manufacturers and calico printers, the products being used as vehicles for colours. The dextrins are also used in the manufacture of paper boxes, oil cloth, wall-paper, and for all kinds of pastes and sizings. The chemically-pure dextrin, known as "American-gum"—another product of Dr. Behr's inventive mind—closely resembles gum arabic in its properties, and is used mainly in the manufacture of confectionery and specialties. Another new product, to which the trade name "Amidex" is being applied, is for all practical purposes a soluble starch, being almost entirely soluble in water of 60° Fahrenheit. It seems to be particularly suitable for the finer grades of textile fabrics. Another new article, "Cereal Flakes," is a product of a dextrin-like character, representing the first stages of the cleavage process of starch. It appears in snow-white flakes, is easily soluble in water, and readily converted into sugar by the diastase of malt. It is well adapted as a base for food specialties of all kinds, infants' foods and foods for convalescents; in many cases it takes the place of sugar of milk, over which, among other advantages, it has that of cheapness, and may, therefore, be employed where sugar of milk is now used, as, for instance, in the manufacture of pharmaceutical tablets, etc.

It is now almost one hundred years since Kirchhoff announced his epoch-making discovery that starch could be converted into a sugar, but while the manufacture of corn starch is an industry of long standing, it was not until after the Civil War that experiments were started to make sugar from corn, the cheapest source of starch in this country. These experiments were successful, and products called "Grape Sugar" and "Corn Syrup" were made, comparing favourably with the sugars and syrups made from potato starch in Germany. The industry grew rapidly, until in the year 1884 the importation of potato syrup and of potato sugar, or grape sugar, fell off to a very small amount, and the exportation of corn products assumed large proportions. Since that time it has grown until it is now one of our important industries. A few figures will serve as an illustration.

During the year 1907 about 50 million bushels of corn were used in the manufacture of corn starch, corn sugar, and corn syrup. The total exports of corn amounted to 83 million bushels. This means that this industry has bought from the farmers more than half the amount of

corn which was shipped for export. The value of corn products is double that of beet sugar or cane sugar produced in this country, the total business done in corn products of this character reaching the sum of 50 million dollars per annum.

The capital invested in the manufacture of corn products amounts to 90 million dollars. The industry gives employment to six thousand men, and expends in wages about 4½ million dollars. It consumes one million tons of coal per year. The total freight amounts to about 4 million tons.

This is a wonderful evolution of an industry, of which at one time it was possible to give the following pathetic account: I am quoting from a standard publication:—

"The manufacture of glucose, or grape sugar, from starch has been a prominent American industry for about thirty years. In March, 1865, Dr. Goessling made glucose under a patent he had procured. The sample exhibited led to the formation of a stock company, which purchased of Goessling, Bradley and Briggs their patent for manufacturing sugar and syrup from Indian corn. The company began the manufacture of glucose in the old sugar refinery in Rose Street, New York. Unfortunately, Dr. Goessling, the German chemist, who was to superintend the manufacture of glucose, died before the first lot of glucose was marketed, and with him perished some of the secrets of manufacture. The small stock of glucose made was stored in the refinery, where later, upon examination, it was found in a solid condition, which alarmed the stockholders, for they knew of no use for grape sugar, the name given to starch sugar in its solid form. Neither knew they how to manufacture the glucose as a liquid substance. Their main dependence, Goessling, was gone, and there seems to have been a lack of push, courage, and foresight on the part of the officers and stockholders of the Union Sugar Company, in that they failed to secure expert chemists to work out the secrets of a process known only to Goessling. The few barrels of glucose the company owned, were sold to the Tribune Association for a nominal sum, for use in the printing rooms, after which the company came to grief, having paid \$600,000 for the patents, subject to a right to manufacture, that belonged to a man named Fox. In 1877 the receiver of the Union Sugar Company sold for \$2.50 the patents it controlled."

Coming now to the manufacture proper of corn syrups and corn sugars, in the works the conversion is carried out by stirring the green starch with a large body of water and subjecting this mixture to high heat under pressure, the process being a hydrolytic one, that is, the starch molecule takes up a molecule of water under formation of dextrose. We add to the water a very small amount of pure hydrochloric acid, for the purpose of inciting and facilitating the catalytic action. I should like to call attention to the incorrect description of the manufacture of glucose, as found in most text books on chemistry, the statement being made universally that the starch is converted into glucose by hydrochloric acid. The fact is, however, that the acid plays only the rôle of a catalyser. The conversion of the starch is performed in large vessels six feet in diameter and about twenty feet high, made of hammered copper one inch in thickness, and called "converters."

By varying the temperature and the time, the action of the starch is changed at will and different products result. As soon as the "test" is obtained, indicating that the conversion has been carried to the desired point, further conversion is arrested by releasing the pressure and neutralising the traces of hydrochloric acid in the mixture with soda ash, practically to the neutral point. By the neutralising, sodium chloride or ordinary table salt is formed, which in no wise affects the taste of glucose, as it is present, of course, only in extremely small quantities. In the case of glucose, the test is obtained in less than ten minutes; in the case of 70 sugar, 80 sugar, or anhydrous sugar, the time has to be lengthened considerably. From the neutralisers, the converted starch, now an almost white "liquor," is run through filter presses, which retain such impurities as proteid matter, fibre, etc. The filter-pressed liquor is run through an evaporator, wherein the gravity is reduced approximately to 30 degrees B \acute{e} .

From here, the liquor is transferred to the filters, which are filled with bone char.

Each batch is run successively over three filters. These filters are 10 feet in diameter and 24 feet in height, and contain approximately 70,000 pounds of bone char each. It will be seen from this that the liquors are run over bone black, representing a height of 72 feet. This is one of the most important operations in the manufacture of dextrose products. The liquors receive a much greater amount of bone char treatment than is the custom in cane sugar refineries. The remaining traces of acid are completely neutralised by the bone char, and the resultant liquor has now a brilliant crystal white appearance.

After a batch of glucose or sugar liquors has been run over the bone char, the latter is thoroughly washed and steamed, then dropped into the kilns, which are maintained at a high temperature, either by oil or coke. During this heating, all foreign carbon is burned off and the bone char emerges from the kilns in a "revivified" condition. It is then conveyed through reels in order to remove the dust, which is produced by the grinding of the particles of the char, and is then transferred to the bins, ready for the filters. Enough fresh bone char is added to make up for the loss occasioned by the powdering in transit.

The glucose and sugar liquors are now sent to the vacuum pans, where they are concentrated to the required density, varying from 42 to 45 degrees Beaumé. The evaporated glucose forms a viscous syrup, whereas the sugar liquors, after cooling, crystallise to white sugars, such as the No. 70 sugar, or to the yellow No. 80 sugar. By a most elaborate process, pure dextrose is obtained in the form of crystallised anhydrous grape sugar. This latter is made by the original process discovered by Dr. Arno Behr, and permits of producing this beautiful product in crystallised form, without the aid of alcohol.

The average composition of these products is as follows:—

	Corn syrup.	70 sugar.	80 sugar.	Anhydrous sugar.
	per cent.	per cent.	per cent.	per cent.
Water	19.0	19.7	11.2	4.0
Dextrose	38.5	70.2	79.9	94.6
Dextrin	42.0	9.3	8.0	0.7
Ash	0.5	0.8	0.9	0.7

The ash consists principally of chlorides.

Corn syrup is sold in tank cars and in barrels, the barrels containing usually about 600 pounds net. It is used principally in the manufacture of confectionery and table syrups. It is used extensively in making preserves, jellies, jams, and marmalades, for which it is preferable in many respects to sugar or cane syrup. The confectionery trade requires corn syrup, not to manufacture a cheaper product, but to manufacture a high grade product. Goods made from corn syrup are not likely to "grain," and creams made from corn syrup will remain smooth and will not granulate like those made from sugar. Gum-drops are made almost entirely of corn syrup.

The No. 70 and No. 80 sugars are employed in the brewing of ales and porters, their use imparting the keeping qualities which are so essential, since these beers are shipped to all parts of the world. The principal consumption of these sugars is, therefore, in Great Britain. Caramel or sugar colouring is also made from these sugars. Anhydrous sugar is used in the after-fermentation of beers necessary to produce carbonic acid gas, the so-called "kraeusening" of beers. It is the best material for that purpose, because, being pure dextrose, it does not contaminate the product in any way whatsoever. It is also used in the wine industry for petiotising wines deficient in sugar.

The use of corn syrup for table purposes has assumed large proportions. These table syrups are usually prepared by mixing corn syrup with a certain amount of cane syrup or refiners' syrup, or molasses or sorghum, the operation being carried out in tanks holding about 100 barrels of syrup. A few statistics will give a fair idea of the magnitude of this particular industry. These data are taken from an address, which I delivered in 1903

at the St. Paul meeting of the National Association of State Food and Dairy Departments. I said at that time:—

"The production of cane syrups in the Eastern and Southern sugar refineries is estimated at 346,000 barrels per annum. Of this, 60 per cent. is sold for export, leaving 40 per cent. for home consumption, equivalent to 138,400 barrels; deducting from this 20 per cent. for syrups used for manufacturing purposes, we find that 110,720 barrels represent the total amount of the home consumption for table syrups from this source.

"Louisiana's output is estimated at 400,000 barrels, which is equally divided between table syrups and manufacturing purposes.

"Add to the above the cane syrup from Georgia, the sorghum from Ohio, Missouri, Kansas, Iowa, and Kentucky, all in all about 80,000 barrels, the table consumption of cane syrups and sorghum will be found to be a little less than 400,000 barrels per year.

"Against this the production of corn syrups for table use aggregates a total of 1,350,000 barrels per annum. These syrups contain on an average about 10 per cent. of cane syrup, equivalent to 135,000 barrels; deducting this from the total of 400,000, we have left 265,000 barrels of cane and sorghum syrups against 1,350,000 barrels of corn syrups, or, in other words, for every barrel of cane syrup and sorghum there are sold five barrels of corn syrup.

"These observations lead to the following conclusions:—

First. The demand for table syrups exceeds by far the supply furnished by the cane sugar and sorghum refineries.

Second. Corn syrups meet this demand.

Third. Corn syrup is a superior table syrup of recognised merit, and a necessary commercial commodity."

That was five years ago; since then the sales of corn syrups have shown a marked increase, so that it seems more correct to state, that for every barrel of cane and sorghum syrups there are sold almost ten barrels of corn syrup.

This syrup business has grown to such an extent that it has been found necessary to build two factories for the manufacture of tin cans and in that way the old, cumbersome method of handling and storing cans is avoided, the object in installing can factories being, not only to reduce the cost of the packages, but to have at all times a ready supply of cans, independent of the manufacturer and the railroads. The Syrup Department also maintains its own printing establishment.

I have attempted to give an insight into an industry, attractive because of the multitude of its products and the almost unlimited possibilities of their further development. Much has been done to bring it upon the high plane it occupies to-day, and much remains to be done. What has been accomplished in this wonderful industry fills one with pride, because it is a great American creation, a typical American industry.

I have indicated that the course of the glucose industry did not always "run smooth." There have been few food products about which more mis-statements have been made than glucose. This may have been due, in a measure, to its somewhat mystifying name "glucose," the derivation of which from the Greek word "glycus" is not known to the layman. Glucose used to be looked upon as an adulterant, if not a poison, and, therefore, destructive to health; the lack of public information in regard to this product was relied upon to propagate an adverse opinion among the masses. The Press has been used unsparingly; even legislative aid was invoked, not excluding Congress, to crush this great and growing industry. But investigation furnished such overwhelming proof of the great value of this manufacture to the people and the country at large, that prohibitory action could never have been justified; as a matter of fact, these misrepresentations have finally resulted in the greatest vindication of glucose.

The investigation referred to was conducted in 1883 by the National Academy of Sciences, a national institution, as you may know, chartered by Congress, the committee appointed for the purpose consisting of the following scientists:—

Professor Geo. F. Barker, University of Pennsylvania.

Professor Wm. H. Brewer, Yale University.
 Professor W. Gibbs, Harvard University.
 Professor Chas. F. Chandler, Columbia University.
 Professor Ira Remsen, Johns Hopkins University.

In their lengthy and thorough report they gave expression to the following conclusions:—

"The starch sugar thus made and sent into commerce is of exceptional purity and uniformity of composition, and contains no injurious substance. Though at best having only about two-thirds the sweetening power of cane sugar, yet starch sugar is in no way inferior to cane sugar in healthfulness, there being no evidence before the committee that maize starch sugar, either in its normal condition or fermented, has any deleterious effect upon the system, even when taken in large quantities."

Although the corn products interests were foremost among the food manufacturers of this country in securing the enactment of a National Pure Food Law, and although they spent large sums of money in improving their processes, so as to meet even the strictest requirements of food laws, the industry found itself, as recently as last year, face to face with the grave situation that after it had established the healthfulness and wholesomeness of its products, the very name of its principal product was now made the subject of an attack. It is hard to understand why the name "Corn syrup" should not give satisfaction to everybody: it certainly satisfies the consumer, who is the principal party to be considered, as it tells him exactly of what the product is made. The main reason advanced why this name was not considered proper was, that far back in 1842 experiments were being conducted in this country for the purpose of extracting from the stalks of the corn a syrup belonging to the sucrose class. It would seem that such a product, if actually made, should be called a "Corn stalk syrup," as the name "corn" applies only to the grain and not to the stalks. "Corn stalk syrup" was the name applied to it in the early reports of the Commissioner of Patents, and the very fact that the experiments were conducted over 60 years ago, and did not lead to any commercial success, clearly prove that they cannot be considered other than abandoned experiments. It is gratifying to note, however, that the highest authorities under the Food and Drugs Act, namely, the Secretaries of Agriculture, the Treasury, and the Department of Commerce and Labour, after a most careful examination of all the testimony submitted in an official promulgation, designated as "Food and Drug Inspection §87," proclaimed corn syrup as the proper name for the product, obtained by a partial hydrolysis of the starch of the corn.

While I have emphasised the importance of corn syrup as a food product, I do not wish to neglect the technical uses to which corn syrup is put. They are innumerable, and it would exceed the scope of this address were I to enumerate them. I do wish, however, to call the attention of my brother-chemists, engaged in technical pursuit, to the great versatility of this product, and I feel that it is not as yet fully appreciated, as perhaps too little was known about its merits, apart from being a food product. The corn products interests always have made it a policy to encourage and foster experiments, looking to a greater consumption of corn syrup and corn sugars in technical fields.

The corn products industry has undergone great changes. Factories have come and factories have gone. What once was considered the best, was later found to barely meet the average. Where once a 500-bushel works was looked upon with awe, a factory grinding 15,000 bushels arouses no special attention to-day. The factory built in Chicago in 1882 was a landmark of that city: it was also looked upon as a model plant: it was perhaps the only factory ever built in this country, having a height of 14 storeys. The idea governing the erection of a works of such huge height was to operate it upon the gravity plan: that is, the corn was elevated to the top floor and from there gradually worked its way down to the warehouse and shipping floors, from where the finished goods were loaded into the cars. It has been amply demonstrated, however, that this method can no longer be considered good engineering, at least not in our industry. The strain on the building, the wear and tear, are too great, and the cost of mainten-

ance becomes too burdensome. Thus it happened that within the last year the old "refinery," as it was known, was razed to the ground, and with it is gone a part of old Chicago and memories of days of toil and effort, of failure and success. "*Sic transit gloria mundi!*"

All that remains, and only for a little while longer, are the tall smokestack, reaching almost 250 feet into the skies, and a few minor buildings, in which some of the specialties are still being manufactured.

In its stead, however, rises Phoenix-like, a new industrial city on the banks of the Drainage Canal, which forms a link of the proposed waterway between the Great Lakes and the Gulf of Mexico. Where, only a year ago, the country in that section was still given over to farming and was full of charming woods, the situation to-day is very different. The prairie is being rapidly transformed into the seat of a great industry. The trolley-car, the great civiliser, has arrived on the scene; contractors have been at work digging and excavating, building foundations and tunnels, and gradually the chaos begins to assume shape. Huge steel buildings rise in the different parts; the latest style of building—re-enforced concrete, can be seen all over. Great difficulties had to be encountered, as, for instance, the raising of the main line of the Chicago and Alton Railroad a height of ten feet in order to reach the docks situated on the Drainage Canal. A view from the Administration Building shows the vastness of the enterprise. This plant, which led to the founding of a new city, called "Argo," will have ultimately a capacity of 60,000 bushels of corn a day. It will cover an area of 120 acres, and will give employment to thousands of men. It is the climax of the development of the industry of corn products: a proud monument to American enterprise, American skill, American ingenuity, American perseverance. It is a monument to the keen foresight of the progressive management of the "Great American Industry of Corn Products," and is no less a monument to the pioneers of this industry, who have made such evolution possible. If a memorial tablet were to be placed on one of those magnificent buildings, among the names inscribed thereon would be found those of H. C. Humphrey, Dr. Giesecke, Thomas Gaunt, my lamented friend and co-worker Lee Harrison, Charles Pope, Dr. Firmenich, the Hamblins, the Matthiessens, and, above all, the name of the man in whose honour we are assembled to-night, Dr. Arno Bicht.

Scottish Section.

Meeting held at Glasgow on Tuesday, March 2nd, 1909.

DAVID J. PLAYFAIR IN THE CHAIR.

THE DETECTION AND ESTIMATION OF DAMMAR RESIN IN KAURI RESIN.

BY SAMUEL STEWART, F.I.C.

Dammar resin, or gum dammar is the product of certain species of *Dammara* and *Hopea*, which grow in Southern India, Borneo, etc., and is obtained from living trees. It comes into the market in various forms, the finer qualities being in large pieces of a clear yellow, and others brownish or reddish. The lower grades are in the form of grains.

The classification of some of the resins is very defective and confusing, as, for example, Manila copal from *Vateria Indica* is known as "white dammar" and kauri copal from *Dammara Australis* is known as "New Zealand dammar." There are thus classed as "dammar" the products of widely different trees and the resins possess very different properties.

In a paper by Robert D. Thomson, M.D., read at a meeting of the Philosophical Society of Glasgow* on 15th March, 1843, it is mentioned that specimens of both

* Transactions Vol. I., p. 124.

trees, *Dammara Australis* and *D. orientalis* were to be seen in the Botanic Garden there, and he evidently looked upon them as giving resin of similar qualities.

Kauri resin, or *gum kauri*, is the produce of a conifer, which is indigenous to New Zealand, and may be "Bush Gum" from living trees, but much more generally is "Fossil Gum," dug out of the ground where old trees once flourished, but now lie buried and decayed. It comes into the market in a great variety of qualities ranging from large clear pieces through all grades to grains and dust. In the lower qualities a considerable amount of what is known as "Swamp Gum" is present, being the original resin greatly altered by the action of air and water into a porous mass.

It is practically impossible to distinguish by the appearance between some of the kinds of dammar and kauri, especially between the kauri chips and red dammar. Both resins are used in varnish making, but the use of kauri gum as an ingredient of the "cement" for linoleum manufacture is that with which the writer is concerned. The relative values of the various grades of kauri for this purpose will not be touched upon in this paper, nor will the question of whether dammar or other resins be more or less suitable for such a purpose be discussed.

The kauri used for this purpose is generally one of the lower grades, as transparency, &c., necessary in varnish making, are not essential. It consists of pieces of varying sizes from dust upwards to chips. In order to obtain as fair a sample as possible for analysis, a quantity of about 1 lb. is taken and passed through three sieves of different mesh. It scarcely matters what the exact meshes be, but, so as to get uniformity, pieces of the wire cloth used in the trade for sorting out into different grades were procured and are used for this purpose. The proportion of the four various grades thus obtained is ascertained by weighing and calculating to per cent., and then 20 grammes in these proportions weighed out and ground together.

About four years ago the question of the possibility of detecting the presence, and if possible, estimating the proportion, of dammar resin in kauri resin became an important one, as it was suspected that a large parcel of gum just received was not genuine kauri; and the great difference in price—about £60 per ton for kauri against about £20 for dammar—was a serious one.

A considerable amount of information as to the sources and general properties of gum resins of all kinds is to be found in various dictionaries and text books, more especially as to their uses for varnish making, and the action of solvents upon them, the latter being generally given as "soluble," "partially soluble," or "insoluble," no indication of the proportions of insoluble and soluble being given. Specific gravity and melting points are also given in some cases, but, although the latter varies considerably for the various resins and might be useful to some extent in assisting to identify definite resins, especially when in a comparatively pure state, it can be of little use in dealing with mixed samples.

A better line of investigation was indicated by such workers as Mills*, who recorded the results of his experiments on bromine absorption and potash absorption, as applied to resins. Since then a great number of determinations of acid, saponification and iodine values have been determined by Schmidt and Erban, Williams, Bottler, Dieterich, &c., and may be found recorded in various publications and collected in a form suitable for reference in "Analysis of resins, balsams, and gum resins," by K. Dieterich.

Confining attention to the question of differences between dammar and kauri resins, a search was made through all available literature on the subject, and it was found that no satisfactory method of determining the presence, and still less the proportion, of these resins in an unknown mixture presented itself. Thus, although K. Dieterich† gives 20—30 as the acid number for dammar, and Williams‡ 6.42 as potash absorption (hot) for kauri as against 2.85 for dammar, and 130.62 as iodine absorption for kauri as against 99.40 for dammar, and Lippert and

Reissiger* acid value: kauri, 64—81; dammar, 33—35; Lewkowitzsch,† on the other hand, gives

For kauri: acid value 37.39, sap. v. 53.84 & I.V. 90.99
For dammar: " " 35.22 " 32.73 & I.V. 127.5.

which shows that such methods of distinguishing these resins are very uncertain. Worstall‡ goes more thoroughly into this determination, and gives his results as follows:—

TABLE I.

	Kauri.		Dammar.
	lumps.	dust.	
Acid value	72	142	24 to 55
Iodine value	170	74	124 to 103

thus recognising the influence of oxidation on these substances. A sample of rock dammar from Burma tested at the Imperial Institute§ showed acid value 31.5, sap. value, 37.1, and it was noted that it was completely soluble in turpentine and partially soluble in alcohol. Any iodine values which the writer has determined have been so erratic that he prefers not to refer to them. As these figures pointed to great uncertainty as to the definite determination of whether a sample of resin could be certified as kauri or dammar or an admixture, no steps were taken to follow on these lines. This being so, it was seen that the whole question would have to be gone into *de novo*, and the most promising line of investigation was that founded upon the observation that nearly all workers noted that some solvents acted differently on kauri and dammar. In turpentine, for example, dammar was noted as soluble, and kauri, often confused with the true dammar, is sometimes mentioned as partially soluble, or insoluble. In alcohol it was noted that kauri was soluble more or less completely according to the strength of the alcohol, whereas dammar was "partially" soluble, and so on with other solvents.

In order to carry out this investigation, samples of recognised genuineness were obtained and about 100 grammes ground and passed through a 40-mesh sieve. The suspected sample was similarly prepared. Working first on the genuine resins, 1 gr. of each was shaken up (cold) with 20 c.c. of the following solvents, and the results are:—

TABLE II.

	Turpentine (Amer.)	Benzol.	Gasoline.
Kauri	Nearly insol.	Largely sol.	Practically insol.
Dammar	Nearly all sol.	Nearly all sol.	Partially sol.

In attempting to take advantage of the marked difference in behaviour towards turpentine the following experiments were made:—

The ground samples were first heated to 100° C., then 1 gr. shaken up with 20 c.c. American turpentine in graduated tubes, and after settling, 10 c.c. of the clear liquid drawn off, evap. at 100° C., adding ether and then absolute alcohol, and the residual extracts weighed:—

TABLE III.

	Results per cent.
Kauri	66.6
Dammar	142.0
Suspected sample	104.0

It was observed that the turpentine had become resinified and was not expelled at this temperature. The increase in weight of the extract from the suspected sample, in view of the very great increase in the case of the dammar, is noteworthy as probably indicating the presence of the latter resin. Had this sample been pure kauri, it is to be expected that it would have given

a figure less than 100. The method is obviously quite useless, however, but is given here, as it was in the course of carrying out this experiment that the method finally adopted was discovered. It was noticed that on adding the ether all the extracts dissolved to clear solutions, but that on adding the absolute alcohol a copious white precipitate was produced with the dammar, a distinct

adding a little absolute alcohol to the residue, and drying at 100° C., the white substance is obtained. It is extremely soluble in chloroform and, after adding the alcohol to the extract, it very soon reaches a constant weight by heating as above. The results shown in Table IV. have all been obtained by the process just described.

Samples shown:—Kauri, 1; dammar, 2; Sample K, 4.

one with the suspected sample, and *none* with kauri. This was confirmed by treating some kauri and dammar with ether and then adding absolute alcohol, when the kauri remained clear, the dammar gave a large white precipitate, and the suspected sample a distinct precipitate. The presence of this white substance, insoluble in alcohol, in the dammar resin and its absence in the kauri pointed unmistakably to a probable method of detecting the former in admixture with kauri. All the samples of kauri and dammar, which had been received at various times as specimens, were tested in this manner, and *without exception* the results were the same—the kauri remained clear and the dammar gave the white curdy precipitate. This reaction was tested by applying it to various mixtures of dammar and kauri in known and unknown proportions, and in every case the presence of dammar could be decided definitely. When trying to apply this reaction to a quantitative estimation of the amount of white substance present it was found that chloroform was a much better solvent than ether, the dammar dissolving completely and rapidly in it, and the kauri giving a pasty mass as with ether. The process as then carried out and still in use is as follows:—2.5 gr. (a convenient quantity) of the sample of resin, finely ground, is weighed out in a tared, pleated, filter paper, the open end tied up with string, placed in a Soxhlet tube, the space being filled up with small glass balls (to admit of a minimum quantity of solvent being used), extracted in the usual way with absolute alcohol, and the extract collected in a tared flask. After several hours it will be found that, if the sample be pure kauri, the filter paper will contain only organic matter (vegetable fibre, &c.), and mineral matter (clay, &c.). By drying and weighing the filter and contents and then igniting and weighing the mineral matter the percentage of these may be found, and the difference noted as kauri resin (pure). Of course, the alcoholic extract may be heated at 100° C. and weighed, but, as a variable amount of volatile matters are expelled, this is not more accurate than estimating it by difference. If the sample be dammar, or a mixture containing it, it will be found that the filter paper will contain, besides the vegetable and mineral matters, some white particles. In this case all that is necessary, after first driving off at a gentle heat the alcohol adhering to the filter, is to replace it in the Soxhlet apparatus and extract with chloroform, collecting the solution in a tared flask. On distilling off the chloroform,

After the results from the first samples of kauri and dammar were obtained, a mixture of these two identical samples was made and analysed by this process. The result, which was very satisfactory, is shown in column 3. As it was likely that different lots of dammar would contain varying amounts of this white substance, it was desirable, whenever possible, to obtain some of the actual dammar resin found to be present in the suspected sample, and in order to do this, the following method was adopted:—

Some of the larger pieces of the resin were picked out, and each tested by rubbing with a drop of chloroform on a glass plate, and on adding a drop of absolute alcohol it was at once seen whether the piece gave the dammar reaction or not. When a sufficient quantity was thus obtained, the pieces were ground up and analysed as usual. From the percentage of white substance found the amount of dammar in the sample was calculated. The figures for dammar resin given in columns 4, 6, and 14 were thus ascertained. The kauri and dammar pieces from sample 4, the alcoholic extracts from 6 and 7, the chloroform extracts (white dammar substance) from 2, 4, 6, 7, and 12 are exhibited. It is obvious, of course, that this method is not applicable in the case of grain or dust gum. In such cases, if dammar be discovered, it is sufficient to consider dammar resin as containing 50 per cent. of the white substance, and by this means the percentage of adulteration is most likely understated. The figures for dammar resin in columns 8, 9, 10, 11, 12, and 13, were so calculated.

This method of testing is convenient for the rapid identification of samples. Recently 17 samples of all grades of kauri and 12 samples of dammar were thus tested, and in every case the results were as anticipated.

A third method of applying the test, which serves as a qualitative one, and also for estimating small amounts of dammar (under 1 per cent.), is carried out as follows:—

0.5 gr. of the finely ground sample is treated in a porcelain crucible by stirring up with chloroform, filtering through a small filter into a test tube, washing once and then adding absolute alcohol. If the sample consists of kauri only, the solution will remain perfectly clear, but if dammar be present a cloudiness or precipitate will appear according to the amount. To render this method available for estimating small percentages of dammar, a mixture of kauri and dammar resin is prepared to contain 1 per cent. of the white substance and on

quantities of this being weighed off and tested in above manner a fairly accurate estimation of the dammar present in an unknown mixture can be made by comparing the amounts of white precipitates obtained. In this connection two instances can be cited, one of which gave a precipitate equal to that given by 0.3 of the 1 per cent. mixture, or 1.2 per cent. dammar, and the other equal to 0.05 mixture, or 0.2 per cent. It was ascertained subsequently that it was quite probable that a small counter sample of dammar had been thrown amongst the lot of kauri in the warehouse.

The thanks of the writer are due to Messrs. Michael Nairn & Co., Ltd., Kirkcaldy, in whose laboratory the investigation was made, for their courtesy in permitting these results to be published.

Yorkshire Section.

Meeting held at Bradford on Monday, March 22nd, 1909.

PROF. W. M. GARDNER IN THE CHAIR.

THE ACCURACY OF THE METHOD OF DETANNISATION OF THE INTERNATIONAL ASSOCIATION OF LEATHER TRADES CHEMISTS.

BY HENRY R. PROCTER.

Considerable doubts have been thrown on the accuracy of the present official method of the I.A.L.T.C. by some German chemists, and especially by the Association of German Extract Manufacturers, who have consistently opposed its adoption, and by implication have thrown doubts on the *bona fides* of the American and English chemists who claimed to obtain exact results. Such complaints were perhaps natural with an unaccustomed process, and especially with an empirical one where absolute adherence to the prescription is essential; and I have hoped that, with experience, the difficulties, and with these the objections of German chemists would disappear. This hope has been largely justified with individuals, but as the German Extract Manufacturers maintain their attitude of opposition, I feel that it is now time, not only to prove the extreme accuracy of the method in capable hands, but to give the fullest possible details of the means by which this can be obtained.

In the first place I will deal with the chroming and washing of the powder, and the obtaining of blank results in which the dry residue of 100 c.c. of water shaken with the powder should be under 5 mgr., as prescribed by the regulations, a figure which several chemists have asserted it was impossible to attain. The following is a full description in detail of the method adopted in my own laboratory for the determination by blank tests of the solubles in chromed and washed hide-powder.

The hide-powder is weighed, its acidity adjusted, and chromed for one hour according to the I.A.L.T.C. regulations.

The chromed hide-powder is then thrown upon a clean piece of linen in the perforated vessel of a screw-press,* or in a funnel, the portions remaining on the sides of the bottle being washed on to the linen with distilled water. The liquid is allowed to drain away, and the powder and linen removed from the press, squeezed by hand, returned to the press, and pressure applied. The more liquid removed at this stage the quicker the powder is freed from chlorides, but care must be taken that pressure is not applied too suddenly, or the linen will burst. The linen with the powder is then removed, and the latter, remaining in the linen all the time, is well broken up by rubbing the cloth between the hands and returned to the press, which is filled up with distilled water. The powder is thoroughly stirred with a glass rod until all the water has

run out, and is squeezed again. It is very essential to keep the powder well stirred, otherwise channels will be formed, through which the water will run with very little washing effect. This process is repeated about five times, 50 c.c. of the last portion of wash-water which can be removed from the powder by pressing being tested for chlorides. It is advisable after having tested the washings, and found them to comply with the I.A.L.T.C. regulations, to give one more washing, before the final squeezing to reduce the water to the necessary quantity ready for weighing. The washing process should be continuous, and on no account should the powder be left to stand. A quantity sufficient for four analyses in duplicate (about 60 grms. air-dried powder) can be washed free from chloride in about 30 minutes, provided the process is continuous. The powder is now ready for weighing, and is transferred from the linen with a spatula to a basin or other convenient vessel for weighing. The last traces of powder may be removed by holding the four corners of the linen together and beating it upon the bench, when the powder will collect in the centre of the cloth. The remaining manipulations are precisely as for tanning analysis, but using 100 c.c. of distilled water instead of tanning liquor.

The following causes tend to too high residues when carrying out blanks:—

1. *Impurities in the distilled water used.*—The distilled water should leave no weighable residue on evaporation of 100 c.c. to dryness.

2. *Soluble matter from the hands* when squeezing the liquid away from the powder after detannisation. The powder in the linen might be pressed against the side of the funnel with a spatula to expel the last of the liquid.

3. *Soluble matter from linen* used after final churning. The cloths should be washed with water alone, nothing in the nature of soap being used, and finally in distilled water before drying.

4. *Imperfect insolubility of the kaolin used.* This has caused serious errors, and the kaolin should be tested before use.

5. *Presence of dust* with the residue in the basin.—The evaporation should be carried out with as little access to dust as possible, and the basin should be transferred to the drying oven as soon as possible after evaporation is complete.

The following table gives the results of such blank experiments with different powders. The determinations in columns I. and II. were executed by various assistants, and those in column III. by students doing tannin analysis for the first time. The results are not selected for accuracy, but contain the whole of the determinations executed at that time under the respective heads. It was subsequently found that the distilled water was not quite satisfactory, but left a residue of 0.0004 gm. which should be deducted from each determination. Similar experiments were made with a sample of Freiberg powder with less satisfactory results, which are not quoted, as no doubt the quality of the powder has since been improved.

Residue from 100 c.c. of Blank Experiments.

The importance of giving at least one additional washing and squeezing after the powder is freed from chlorides sufficiently to answer the prescribed chromate test is shown by the following results. Probably if the amount of N/10 silver nitrate allowed were reduced from 4 to 2

*The ordinary German fruit-press costing 15s., and holding about 1 litre is found to be very satisfactory. It is convenient to have one or two of the inner vessels varying in size for different quantities of powder.

As regards concordance of analyses, the following figures may be given with regard to 31 analyses carried out in the University Laboratory by various analysts to test whether any difference in results existed between American and Vienna powders. These analyses were done in the course of ordinary commercial work with no greater attempt at accuracy than is made with every analysis which is executed, and each figure represents a complete pair of duplicate analyses, such as are always done for commercial purposes; and they include the whole of the analyses done to compare the powders without selection or rejection, and embrace sumach, lentiscus, mimosa and mangrove barks, chestnut, and oakwood extracts.

They are therefore in no sense "parade analyses."

hide-powder according to the I.A.L.T.C. prescription is a method of great accuracy, and quite as exact as any ordinary chemical determination such as that of moisture by drying, and that two different hide-powders of good quality separately chromed and washed and brought to the same standard of acidity will give absolutely identical results. Now this detannisation is the only point in which the present official method differs from the old one, and so far as my experience goes, it is impossible to produce a series of the same concordance by the filter method with any powder, however carefully prepared.

It may be urged that all this does not prove that different analysts with different samples will get results of corresponding accuracy; and I agree that it does not. No imaginable method will avoid the frequent errors which arise from inexact sampling by clients, and no method will prevent the carelessness and incompetence of unconscientious chemists, but the results quoted show that such differences are avoidable by skill and careful work, and do not depend on differences of hide-powder, or any cause beyond the control of the chemist.

It has been suggested, that while analyses done by a chemist as duplicates show a satisfactory concordance, it is difficult for him to repeat the result at some future time; and it is impossible to prove that this is not the case, especially if a new sample must be drawn, since few extracts remain constant in strength, but differ in

				Mean	0.00006

To sum up results, it may be observed that the greatest divergence in any pair is 3 milligrams, which in an oakwood extract corresponds to about 0.13 per cent.; the mean difference is under 1 milligram, including errors both ways; and the total sum of the differences, subtracting those on one side from those on the other, is under 1 milligram. This proves that detannisation by shaking with

*The test of 4 drops of AgNO_3 amounts to about 2.3 mgr. NaCl on 50 c.c. of the wash-water. No doubt on making a blank test by shaking with only 100 c.c. of water, a larger proportion would be obtained. In case of doubt it is therefore wise to make such a blank test on the actual powder which is afterwards used for analysis.

solubles and tannin by fermentation and by settling of the difficultly soluble constituents, so that no two samples taken at different times can be guaranteed to be absolutely alike. Solid extracts also vary in moisture and possibly in solubility, and fair sampling even with the greatest care is by no means easy.

The following non-tannin determinations, however, in which analysis of the same solution was conducted by different assistants, each chroming their own hide-powder and in ignorance of each other's results, prove that the determination of non-tannins at least will agree if performed on identical materials. Here again all results good and bad of a series are quoted.

Results of repeat analyses carried out by independent operators.

As a further test of the comparative accuracy of the official determination of non-tans, I applied to a number of English extract manufacturers and large dealers whom I knew to have been making extensive tests of the concordance of the results of different chemists under the new method, for information as to the results obtained; and received in all, details of the analysis of 20 different extracts each determined by two or three different chemists, of whom in many cases I do not even know the names. In order to determine the degree of concordance attained the average result on each material was determined, and the sum of the differences from these averages was taken without regard to whether + or —. One set of three analyses was rejected on account of an obvious clerical error in one analysis which added to 102.3. Of the remaining 51 analyses the average difference from the mean was 0.39 per cent. In order to compare to some extent the accuracy of the work and sampling, the water determinations of the same extracts were similarly compared, and showed an average error of 0.31 per cent. As a further check, the non-tannin results of the 66 analyses by the filter method with Prof. Paessler's "lightly chromed powder" carried out by Messrs. Arnoldi, Bösch, Moll, Philip, Siehling, Seidel, and Veit for the German Analysen-commission, and published in the report by Prof. Paessler (Collegium 218 *et seq.* 1908), were similarly treated; and showed an average error of 0.42 per cent. As in this case the samples were sent out as identical by Prof. Paessler himself, together with an identical hide-powder, and the names given preclude the supposition of careless or incompetent work, while those by the shake method were by ordinary commercial chemists, with commercially drawn samples, and any hide-powder, the comparison of the results is interesting.

Most of these extract manufacturers now admit that present results by the shake method show better concordance than the former with the filter, and several of the more important are warm supporters of the change; and complaints now centre rather on the defects of colour-testing than on the actual tannin determination.

In conclusion I may say that the evidence I have brought seems to me absolutely to establish the superior accuracy (or at least concordance) of results of the shake-method as compared either with the old filter-method, or with Dr. Paessler's with lightly chromed powder, and though, as Chairman of the Commission, I shall be glad to discuss any improvements which may be suggested either in accuracy or rapidity of execution, I consider that the controversy as regards the superior accuracy of the old filter method is now closed so far as I am concerned.

SOME INDIGO PRODUCTS FROM NORTHERN NIGERIA.

BY A. G. PERKIN, F.R.S.

In a previous communication (this J., 1907) an account was given of the investigation of the so-called "Gara-plant" which had been forwarded by the authorities of Sierra Leone to the Imperial Institute for an examination

of its dyeing properties. This product, which consisted of the dried and fermented stems and leaves of the *Loncho-carpus cyaneus*, a woody climber of from 10 to 40 feet in length, contained indigotin to the extent approximately of 0.65 per cent. Somewhat more recently Prof. Dunstan forwarded to me two other indigo products also from West Africa, but this time from Northern Nigeria, one of which closely resembled the Gara plant of Sierra Leone, whereas the second consisted of specimens of indigo in the lump form.

For the examination of the former, which consisted of a mixture of leaf and stem of a dull greenish-blue colour, 200 grms. of the material was repeatedly extracted with boiling water, which removed (as had also been the case with the (Gara plant) a very large quantity of a brown substance. The residue was then steeped in a large bottle repeatedly with alkaline hydrosulphite solution, the yellow extract oxidised by means of air and to render the colouring matter thus precipitated in a more granular form, the mixture was boiled and treated with an excess of salt. The product was collected, washed, first with water, and then with boiling dilute hydrochloric acid, and after removal of the acid was allowed to dry at the ordinary temperature, so that the substance thus obtained was in a porous condition and was easy to powder. For purification it was extracted with boiling nitrobenzene, and the crystals collected and weighed. By operating in this manner an approximate idea of the colouring matter present in the material was obtained, though this value is probably a little too low.

Found Indigotin = 1.3035 grms., which is equivalent to 0.65 per cent., a result curiously enough identical with that which was previously given by the "Gara" plant.

Somewhat recently the authorities of the Imperial Institute obtained for the author some quantity of the air-dried leaves of the *Loncho-carpus cyaneus* from Sierra Leone, in order that a chemical examination of the indigo-yielding principle contained in the plant could be carried out, and also that a better knowledge could be obtained of its commercial possibilities. Unfortunately, however, the leaves on arrival were found to be devoid of colouring principle, and as they contained some indigotin it was evident that the former substance had been hydrolysed by fermentation. It is quite possible, of course, that the indigo-yielding substance of this plant may consist of the isatin which has been shown by Beyerinck (Proc. K. Akad. Wetensch. 1900, 3, 101) to exist in wood, and which differs from the better known indican of the *Indigofera*, by its instability, which has not yet permitted of its isolation in a pure condition. Should such be the case, an effective chemical examination of this plant can only be made on the spot. The specimen was, however, useful for reference, for as there was a considerable similarity between this and the Northern Nigerian product, it seemed likely that they were identical, and a comparison of the samples very kindly carried out by Prof. V. H. Blackman of the Leeds University, leaves little doubt that this is the case. Thus it was found by an examination of the materials in question, that the stems of both possessed a similar arrangement

of epidermis, selenchymaring, vascular bundles and pith, and that in the leaves the well-marked arrangement of hairs (characteristic of the *L. cyanescens*) was present. The form and arrangement of the stomata, and of the veins and the structure of the upper and lower epidermis of the leaf was also identical in the two cases, and as a result Prof. Blackman states:—"The unnamed plant must therefore be *L. cyanescens* or some very closely related form." The specimens of indigo above referred to, and which consisted of small pyramids, weighed on the average about 7 grms., possessed in parts a coppery lustre, and were of a friable nature. For the analysis of this product in regard to its percentage of indigotin and indirubin, a somewhat novel method devised by W. P. Bloxam and the author was employed. As certain experiments which are being carried out by this process are not fully completed, the details are reserved for the full communication which will shortly be made on this subject. In addition to the amount of colouring matter which was present, a determination of the mineral matter soluble in hydrochloric acid, of the substances dissolved by alkali after this treatment, and of the amount of other impurities contained in the indigo was carried out. The results are embodied in the following table.

	I. Per cent.	II. Per cent.
Moisture.....	5.38	—
Indigotin.....	21.47	21.65
Indirubin.....	1.33	1.10
Brown matter (indigo brown) soluble in sodium hydroxide.....	12.15	—
Organic matter, soluble in HCl.....	10.83	—
Organic matter (plant debris) insoluble in Nitrobenzene.....	9.59	—
Inorganic matter soluble in HCl.....	19.20	—
" " insoluble in HCl.....	29.10	—
	100.05	

A complete analysis of the mineral matter (39.3 per cent.) was not performed, but it was ascertained that whereas the portion insoluble in hydrochloric acid was quite colourless and consisted almost entirely of silica, the dissolved matter contained iron and calcium salts, the latter in considerable quantity. The existence of this very considerable amount of inorganic substances in the indigo naturally suggests adulteration, but on the other hand it is possible that this may have been added as a crude lime preparation during the process of manufacture, to assist both in the more rapid oxidation of the fermented plant solution, and to complete the precipitation of the indigo thus formed. The presence of indirubin supports this latter contention, as this colouring matter is always formed to some extent when indoxyl is oxidised in the presence of lime water, or indeed under any other faintly alkaline conditions.

To be certain that the colouring matter present in this product was in reality indigotin, and not some closely allied derivative, a nitrogen estimation of the substance isolated in the usual manner by means of nitrobenzene was carried out with the following result:—

Found N = 10.75.

$C_{16}H_{10}N_2O_2$ requires N = 10.69 per cent.

With regard to the botanical origin of this indigo, no information could be given by the Imperial Institute, but it was stated that in Northern Nigeria indigo is produced not only from the *Loucho-carpus cyanescens*, but probably also from certain species of *Indigofera*. This is in harmony with the following extract taken from the "Miscellaneous Trade Notices" of this Journal, 1889, p. 584: "Yoruba land* is famous among West Africans for its blue dyeing. Over it are found many botanical species that yield the indigo of commerce."

Fortunately, however, one of the cakes of this indigo was found to contain some fairly large fragments of stem, and these it was only reasonable to anticipate were derived from the plant which had been employed for the manufacture of this colouring matter. The examination of these was again very kindly undertaken by Professor Blackmann, who pronounced them to be very similar and probably identical with the leaf stems of the *Loucho-*

carpus cyanescens, and there is thus practically no doubt that these samples of indigo had been derived from this plant.*

It is thus interesting to find that both in Sierra Leone and Northern Nigeria, districts of Western Africa which are several hundred miles apart, the same plant *Loucho-carpus cyanescens* is employed for the manufacture of indigo. In Bancroft's "Philosophy of Permanent Colours" (Vol. I, 1813, 168) mention is made of the introduction of the "Taroom akkar," which grows in Sumatra and is probably the *L. cyanescens*, into Sierra Leone, so that whether it is really native of this part of West Africa does not seem to be certain.

A point of some interest is afforded by the occurrence of brown matter in both these West African indigo products derived from the *Loucho-carpus cyanescens*, for such appears to be always present in natural indigos, whether produced from the *Polygonum tinctorium*, the various species of *Indigofera*, or the wood plant, *Isatis tinctoria*. It has long been considered likely that these brown substances represent a "waste" of colouring principle, and recent work in the University of Leeds indicates as probable that indigo brown itself may originate in this manner. That indigo derived from such distinct varieties of plant should invariably contain indigo brown certainly lends support to this view.

In an earlier paper, "Notes on West African Indigo," by Rawson and Knecht (Jour. Soc. Dyers and Colourists, 1888, 66; this J., 1888, 429) an account has been given by these authors of some indigo products which had been sent to this country by Sir T. Goldie, Governor of the Royal Niger Co. These consisted of the leaves of a plant in ball form which contained indigotin to the extent of 0.51 per cent, and (b) small conical masses of indigo which on analysis were shown to possess the following composition:—

Indigotin, 39.12. Indirubin, 4.75 per cent.
Foreign organic matter, 29.17. Ash, 19.66 per cent.

Unfortunately the botanical origin of these specimens was lacking, and in view of the statements that indigo is produced in Nigeria from a variety of plants, it is impossible to conjecture whether these indigo samples of Rawson and Knecht had also been derived from the *L. cyanescens*. It is interesting to note in connection with the leaf product described by these authors, that it contained a large quantity of a brown substance† soluble in boiling water, and the presence of this they considered was probably due to changes which had involved a loss of colouring matter.

Finally, it is to be remarked that with the exception of a patent taken out by Calmette (this J., 1902, 38) for the production of indigo from the *L. cyanescens*, the author has been unable to discover any allusion to this plant in the literature, and information appears to be entirely lacking, as to its capabilities in this respect, as compared with those of the better known indigo plants.

ADDENDUM.

Since the communication of this paper, it has been possible, owing to the courtesy of Prof. W. Gardner, to carry out a botanical examination of the leaf product described by Rawson and Knecht, samples of which had been preserved in the museum of the Bradford Technical College. As a result it has been found that these leaf fragments possessed the same structure as those of the *L. cyanescens*, and there can thus be little doubt that they have also been derived from this plant. On the other hand, the "ball" form of this product has a very distinct appearance from the "Cora ball" of Sierra Leone, previously described (*loc. cit.*), and indicates that in Nigeria a different process of native manufacture is employed.

*Prof. Blackman states, "I see no reason for believing that it is other than the *L. cyanescens*."

†There is evidence that in such crude fermented preparations of indigo yielding plants, the presence of this brown matter is usual. A somewhat similar product to those derived from the *L. cyanescens*, and which is known as "Aidama" indigo, and is produced from a perennial lush cultivated in Southern Japan, has been examined by the author, and found to contain very large quantities of such an impurity.

* Yoruba land is a district of Nigeria.

DISCUSSION.

Prof. W. M. GARDNER said it was uncertain whether natural indigo would or would not be entirely superseded by synthetic indigo. A great deal might still be done to improve the production of natural indigo, to which end an examination of indigo-producing plants from all parts of the world would be of service. Plants yielding better supplies of the product might still be found and the possibilities of improvement by proper selection of seed and cultivation of wild species should be investigated.

Mr. F. W. RICHARDSON asked if any analytical figures were forthcoming to show the relationship between the amount of indigotin, indirubin, and brown colouring substance at different periods in the growth of the plants. Wastage by conversion of the indigotin to the brown colouring substance seemed probable and such a series of figures would locate this loss.

Mr. A. G. PERKIN, in reply, said that experiments carried out some years ago by Rawson showed that the

quantity of colouring principle present in the leaf of *I. Sumatrana*, varied according to the season; thus in one instance the leaves yielded in May 0.30 per cent. of indigotin and in August 0.76 per cent., whereas in November the quantity had fallen to 0.25 per cent. With regard to the formation of brown products during the manufacture of indigo, which appeared to represent a loss of colouring matter, a very large quantity of pure indican had been prepared in order to study this point, and it was found that though indoxyl when oxidised by air was converted mainly into indigotin, certain secondary reactions took place at the same time. From the work of Mr. Bloxam and his colleagues, there was evidence that in southern India the indigo plant contained more indican than that growing in the more northern districts. It was probable that the natural indigo industry would hold on for some time, and there was no immediate prospect of it dying out. Natural indigo might yet be more economically produced, though it appeared to him to be doubtful if synthetic indigo could be made much more cheaply than it was at present.

Journal and Patent Literature.

PATENT SPECIFICATIONS may be obtained by post by remitting as follows:—

English.—8d. each, to the Comptroller of the Patent Office, C. N. Dalton, Esq., Southampton Buildings, Chancery Lane, London, W.C.

United States.—1s. each, to the Secretary of the Society.

French.—1 fr. 25 c. each, to Belin et Cie., 56, Rue des Francs-Bourgeois, Paris (3e.).

German.—1 mark each (with full particulars), to Kaiserlich Patentamt, Berlin, Germany.

I.—PLANT, APPARATUS, AND MACHINERY.

PATENTS.

Drawing liquids through other liquids of greater density, and viewing same in their passage. R. Wood, Bolton, Eng. Pat. 4834, March 3, 1908.

The lighter liquid (*e.g.*, oil or ether) enters by the pipes, O, into the box, C, and passes upwards past the ball-valve D, into the transparent sight tube, E, which is filled with the heavier liquid (*e.g.*, water), the latter being prevented from escaping from the tube, E, by the ball-valve, D. The lighter liquid rises through the water and can be seen, and the quantity passing judged, through the transparent tube, E. From the top of E, the lighter liquid escapes through the passage, g, past the ball-valve, H, to the passages, c, P, P', Q, which are connected to spaces in which there is a slight vacuum.—W. H. C.

Separating materials of different specific gravity. H. L. Lewis, Lammeston, and The High Moor Syndicate, Ltd., London. Eng. Pat. 6253, March 20, 1908.

The materials to be separated are fed along with water into the upper end of a long sluice-box, *a*, on the bottom of which a layer of coconut matting, *b*, is spread. Above the matting a number of perforated plates, *c*, are arranged step fashion, the front of each plate overlapping the back of the next, but supported a little distance above it, so as to leave a space, *e*, through which the water can flow. The back of each plate is bent over or has an angle-piece fastened to it to form a weir, *d*. The solids are carried down by the flow of water, pass through the perforations, and are caught behind the weirs, the water flowing on. When sufficient material has collected, the plates are taken out and the solids removed, the heavier bodies being found nearer to the upper and the lighter bodies nearer to the lower end of the sluice-box.—W. H. C.

Printing inks and the like: Moving-stirrer apparatus for mixing —, E. and H. Bush, Leeds. Eng. Pat. 8623, April 18, 1908.

The vertical shaft by which the stirrer-blades are rotated in the mixing pan is made in two parts and passes through

a bracket supported above the pan, being rotated by gearing from above. The two parts of the shaft are connected by a coupling or sleeve which is attached to a hand lever. On raising the lever, the coupling is lowered over the junction and the scraper is rotated. On depressing the lever, the coupling is raised, thus exposing the joint so that the lower portion of the shaft can be removed. —W. H. C.

Pyrometers, or apparatus, for ascertaining, or measuring high temperatures. A. W. Dixon and E. Middleton, Sheffield. Eng. Pat. 13,360, June 23, 1908.

The radiations from the hot body are focussed by a lens and thrown upon a cell formed of selenium or other light-sensitive substance. The selenium cell is connected to a galvanic battery, a rheostat, and a galvanometer by which the change in resistance of the cell due to the radiations is indicated. —W. H. C.

Pyrometer. J. Kirner. Fr. Pat. 395,229, Oct. 14, 1908.

Two or more U-tubes, 1, 2, are immersed in the vessel the temperature of which is to be ascertained. The bend of each tube is filled as shown with an alloy or mixture of salts having different fusion points. One branch, 3, 4, of each tube is connected to a manometer, 6, 7, filled with liquid, and the other branches are connected to the apparatus, 5. On causing the pendulum, 9, to oscillate, the plunger, 8, is alternately raised and lowered, and the pressure of the air in the chamber, 5, rapidly alternates. If the substance in the U-bend is molten, then the alternations of pressure are communicated to the manometers, 6, 7, and are rendered visible, but if the substance is solidified, then the alternations of pressure are not transmitted, and the liquid in the manometers remains stationary. By observing the behaviour of the liquid in the manometers, it is possible to ascertain which of the substances in the U-tubes is melted and which is solid, and consequently the limits between which the temperature of the vessel must lie. —W. H. C.

Strainer; Continuous. — Aktiebolaget Separator, Stockholm, Sweden. Eng. Pat. 16,017, July 28, 1908. Under Int. Conv., Aug. 1, 1907.

The fluid to be strained is fed into a horizontal cylinder within which a horizontal cylindrical strainer is rotated. The liquid passes through the strainer into the interior, from which it is discharged through one of the trunnions by which the strainer is supported and rotated. The solids are continuously removed from the surface of the strainer by scrapers mounted on a frame and rotated relatively to the strainer. The scrapers cause the solids to move along the interior surface of the stationary cylinder to the opposite end from that through which the liquid escapes. The solids then enter an enlarged portion of the cylinder within which a bucket-wheel is rotated, by

which they are elevated and discharged on to a trough passing through the upper part of the end of the enlargement. —W. H. C.

Separating minerals or other crushed solid materials from liquids. A. J. Arbuckle and A. Osborne. Fr. Pat. 393,990, Sept. 5, 1908.

The mixture of solids and liquid is fed continuously into a conical vessel and the solids which settle to the apex of the cone are continuously withdrawn from an opening at the bottom by one or more rotating drums. —W. H. C.

Steam and compressed air pipes, joints, and the like; Process for the treatment of — and a composition to be employed therein. P. McCarthy, Blaengwynfi, and Tuck and Co., Ltd., Cardiff. Eng. Pat. 18,636, Sept. 5, 1908.

A MIXTURE of about 96½ parts of cylinder oil, 3 parts of finely-ground graphite and ½ part of steatite is introduced, by a device similar to a sight-feed lubricator into the steam or air mains at a point near their commencement. The mixture is said to be carried along by the steam or compressed air, and is spread over the interior surface of the main, forming a coating which preserves the pipes from rust or corrosion and fills up any small cracks or leaks. —W. H. C.

Introducing gases into liquids; Apparatus for —. S. P. A. Wenström, Oskarshamn, Sweden. U.S. Pat. 913,596, Feb. 23, 1909.

The gas is introduced through a hollow, perforated, rotating shaft which is mounted horizontally within the vessel containing the liquid. Curved baffle-plates are mounted transversely across the shaft, and inclined thereto, and are rotated with it for the purpose of breaking up the streams of gas as they issue from the perforations. —W. H. C.

Desiccating fluid substances; Apparatus for —. W. S. Osborne, Hyde Park, Mass. U.S. Pat. 913,760, March 2, 1909.

The liquid to be desiccated is spread as a thin film by the spraying device, 7, upon the surface of the endless metal belt, 1, which passes round the drums, 2, 3, and is enclosed in the casing, 9. The drum, 3, is rotated and the drum, 2, is heated internally. Air heated by the apparatus, 11, is drawn by the fan, 10, over the surface of the belt as indicated by the arrows in the opposite direction to that taken by the belt itself. The desiccated material is removed from the belt by the scraper, 12. —W. H. C.

Drying-machine. J. H. Ryan and J. F. O'Toole, Pittsburg, Pa. U.S. Pat. 913,774, March 2, 1909.

The material is allowed to fall through a chamber in which a number of "flue-pans" are supported one above the other, and a current of drying medium is caused to pass upwards through the chamber. Each "flue-pan" has rows of parallel A-shaped partitions on its upper surface, spaced apart, leaving openings through which the material falls, the upper edges of the partitions in one pan being directly beneath the openings in the pan above. —W. H. C.

Filter-press plate. J. W. Biles, Louisville, Ky. U.S. Pat. 914,476, March 9, 1909.

The plate is formed of a central web with vertical ribs on each face extending beyond the periphery of the web. A rim is secured to the ends of the ribs and extends beyond the periphery of the web. Openings are provided for the exit of the filtrate by extending some of the ribs to the edge of the rim.—W. H. C.

Distilling apparatus. S. Hamburger. Ger. Pat. 203,902, July 21, 1907.

In column stills of the usual type, instead of the pipes through which the steam (or vapour) rises being fixed tightly in the plates, they are inserted loosely, with a free annular space, through which the liquid being distilled flows downwards instead of through the usual overflow pipes. In this way, it is claimed, a more intimate contact between the vapour and liquid is attained. The apparatus is stated to be especially useful in the preparation of formic acid.—A. S.

Latent heat of vaporisation of liquids; Regeneration of —. E. Nobel and S. Bessonoff. Fr. Pat. 395,108, Oct. 9, 1908.

The vapour given off in a tubular evaporator is aspirated by a pump, compressed, and returned through the casing surrounding the tubes of the heater, where it gives up its latent heat to liquid circulating through the tubes. The pump is worked by a heat engine, the exhaust gases being circulated through a separate tubular heater in the evaporator to utilise their heat.—W. H. C.

Evaporation of liquids in vacuo; Apparatus for the —. M. Töpfer. Ger. Pat. 207,152, June 15, 1907.

In apparatus of the type in which a heated rotating drum dips into the liquid to be evaporated, contained in an outer casing from which the air can be exhausted, it is proposed to use a trough, which can be readily removed from the casing for cleaning, etc., for holding the liquid. The trough is mounted on rollers which run on rails fixed in the outer casing. Gutters are provided around three sides of the trough to catch any condensed liquid falling back from the drum, and to prevent oil from the bearings supporting the drum from running down into the trough. The trough is connected with a vessel, outside the casing, which contains the liquid to be evaporated and is provided with a float, whereby the flow of liquid to the trough is regulated.—A. S.

Filter press; Power —. E. H. Alvord, Seattle, Wash., U.S.A. Eng. Pat. 14,444, July 7, 1908.

SEE U.S. Pat. 894,996 of 1908; this J., 1908, 886.—T. F. B.

Separating comminuted ores or other solid matter from liquids; Means for —. A. J. Arbuckle and A. Osborne, Belgravia, Transvaal. Eng. Pat. 17,756, Aug. 24, 1908.

SEE Fr. Pat. 393,990 of 1908; preceding.—T. F. B.

Separating solid bodies from liquids by cooling; Apparatus for —. P. Porges, Vienna, and R. Neumann, Brünm-Königsfeld, Austria. U.S. Pat. 914,183, March 2, 1909.

SEE Fr. Pat. 390,816 of 1908; this J., 1908, 1101.—T. F. B.

II.—FUEL, GAS, AND LIGHT.

Sampling coal; Accuracy in —. E. G. Bailey. J. Ind. and Eng. Chem., 1909, 1, 161–178.

It is pointed out that coal can never be satisfactorily bought and sold on the basis of analyses unless detailed conditions of sampling are rigorously fixed and adhered to, as otherwise errors due to sampling will frequently overshadow variations in quality. By the present methods of sampling, errors of 3–5 per cent. in the amount of ash are of ordinary occurrence and errors of from 15 to 30 per cent. are frequently encountered. The deviations of the results of individual determinations of ash from the average result closely follow the probability curve, and hence the error of sampling by a given method can be

calculated by the method of least squares. The most important factor to be considered in sampling coal is stated to be the "size-weight" percentage, *i.e.*, the percentage of the largest pieces of slate, etc., to the total weight of the sample previous to its last division or quartering. The weights of pieces of slate and coal of various sizes (4-in. bar screen to 80-mesh sieve) were determined and are given in a table and in curve-diagrams. From a knowledge of the relation existing between the "size-weight" percentage, the amount of ash due to slate, and the possible error, it is stated to be feasible to take a sample of any coal with an assurance that the results will be accurate within certain limits. A series of experiments with a semi-bituminous coal containing about 5 per cent. of ash in the form of slate and other impurities in addition to the ash of the coal itself, showed that if a maximum error of 2 per cent. is not to be exceeded, and the probable error is to be less than 0.4 per cent., the "size-weight" percentage must be less than 0.1, whilst it must be as low as 0.01 per cent. if the maximum error is not to exceed 1 per cent., with a probable error of nearly 0.2 per cent. With a gradual increase of the "size-weight" percentage, the maximum and probable errors rise rapidly. The results all point to the importance of taking a large initial sample, and the following data are given, based on a "size-weight" percentage of 0.01 and a coal containing 5 per cent. of ash in the form of slate and other impurities.

Size of slate.	Weight of largest piece of slate.	Original sample should weigh.
inches.	lb.	lb.
4	6.7	39,000
3	2.5	12,500
2	0.75	3,500
1½	0.38	1,900
1¼	0.24	1,200
1	0.12	600
¾	0.046	230
½	0.018	90

With respect to the size to which the sample should be broken before quartering or dividing, the figures given are: 7500 lb. sample, 2 ins.; 3800 lb., 1½ ins.; 1200 lb., 1 in.; 460 lb., ¾ in.; 180 lb., ½ in.; 40 lb., 2-mesh; 5 lb., 4-mesh; ½ lb., 8-mesh; ¼ lb., 10-mesh. If the laboratory sample is crushed to 2-mesh size, it should not be divided to less than 8300 grms.; 4-mesh size, not less than 1100 grms.; 8-mesh, 120 grms.; 10-mesh, 55 grms.; and 20 mesh, not less than 3 grms.—A. S.

Sulphur in coal and coke; Determination of —. M. Holliger. Z. angew. Chem., 1909, 22, 436–449, 493–497.

The author has made a comparative study of the methods in common use for the determination of sulphur in coal and coke. The conclusions arrived at are: (1). Eschka's method for total sulphur is liable to be inaccurate with coals containing more than 2 per cent., and the process of Hundeshagen (this J., 1893, 465, 1062) gives results which are no better. (2). Sauer's method of determining the so-called volatile sulphur should, especially with coals yielding much gas, be modified as follows:—The combustion tube is constricted to 5–7 mm. for 3–5 cm. of its length near the centre, the space being filled with pieces of platinum wire, and this contact substance is strongly heated before the boat is pushed into the tube; the gaseous products are passed through bromine water or 1 per cent. hydrogen peroxide solution, the stream of oxygen being very carefully regulated. This is regarded as the most reliable method of determining volatile sulphur; that of Pfeiffer (this J., 1905, 943) is only suitable for obtaining rapid approximations. (3). The sodium peroxide method of determining total sulphur (this J., 1901, 4131) may be used where speed rather than absolute accuracy is essential; a stout platinum wire should however be used for the ignition instead of an iron wire; a more dilute chromate solution should be employed; and the liquid containing the chromate, after neutralisation by ammonia, should be transferred to a graduated cylinder and an aliquot part of the clear liquid titrated. (4). Accurate values are rapidly obtained with the calorimetric bomb, but sulphur

may remain in the ash, if the proportion of this be high, and it is sometimes necessary to add a substance capable of raising the temperature of combustion, in order to ensure complete oxidation of the sulphur. (5). Brunck's method (this J., 1905, 1086) in all cases gives accurate results, and the author considers this the most suitable method for determining total sulphur, but it should be modified as follows:—Platinum is used as a contact substance in the combustion tube and hydrogen peroxide solution as an oxidising absorbent; after combustion, the contents of the platinum boat are treated at once with hydrochloric acid and the mixture evaporated to dryness on the water-bath, the hydrogen peroxide solution being made alkaline, boiled to decompose excess of the reagent, and added to the residue; the whole is then acidified with hydrochloric acid and filtered from the silica, and the sulphuric acid determined gravimetrically, titration being inadmissible. The determination of volatile sulphur is looked upon as of little practical value, since its amount depends on the conditions of burning, and results obtained by combustion in oxygen cannot, therefore, indicate what would obtain in an ordinary furnace. The sulphuric acid produced in the above processes of determination may in most cases be titrated, either by the benzidine method, as modified by Friedheim (this J., 1907, 116) or by Bruhn's modification of the chromate method, which should be carried out in the following manner:—An aqueous emulsion of barium chromate, precipitated from boiling solution, is prepared so as to contain about 0.05 gm. of barium chromate per c.c., and 5 c.c. of this well-shaken mixture diluted with 50–100 c.c. of water, are acidified with 1 c.c. of strong hydrochloric acid, and added to the boiling solution to be tested; boiling is continued for some time, and then the excess of barium chromate is precipitated with ammonia, the excess of ammonia boiled off, and the filtered liquid cooled in a closed flask; 20 c.c. of strong hydrochloric acid and 20 c.c. of 10 per cent. potassium iodide solution are then added, the solution made up to 500 c.c., and, after half an hour, titrated with thiosulphate.

F. SOHN.

Lighting gas: Determination of the heating and illuminating power of —. N. Teclu, J. prakt. Chem., 1909, 79, 165–171.

Since the heating power of illuminating gas and the expansive force of a mixture of the gas and air when exploded, both depend essentially on the temperature produced by combustion of the gas, the author makes use of the relation between the two effects mentioned in order to obtain a measure of the heating power of the gas.

The apparatus used is shown in the figure. The glass globe, A, holds 1 litre. It has three openings, 2 cm. wide: in the upper one the glass tube, B, is fixed airtight; in the lower one, the tube, C, 1 cm. wide, is placed loosely, whilst over the third opening, fits loosely the aluminium cap, D, which is fixed to the pendulum, G. In using the apparatus, the tap, K, is closed, and the illuminating gas is passed into the apparatus through the tube, C; the gas escaping at B is, after a time, lighted. After 30 seconds the gas supply is cut off. The flame immediately becomes smaller, and air is drawn into the globe through the lower and side openings; subsequently the luminous flame becomes blue and then splits into two cones in the known manner, the outer one burning at the mouth of the tube, whilst the other travels down into the globe and explodes the mixture of gas and air therein. The effect of a definite aliquot portion of the force of the explosion is registered by the movement of the pendulum. Experiments of this kind showed that different samples of illuminating gas had a heating power greater by from 0.36 to 9.65 per cent. than that of a mixture of equal volumes of hydrogen and methane. The method may also be used for obtaining a measure of the illuminating value of the gas, by observing the time which elapses between cutting off the gas supply and the explosion. This time depends upon the difference between the sp. gr. of the gas and of the air, and in general the illuminating power of gas increases with its sp. gr., the constituents valuable as illuminants being heavy hydrocarbons. If the proportions of carbon monoxide and dioxide be greater than normal, the sp. gr. is increased, and the illuminating power diminished, but in such cases the ratio between the heating power and the illuminating power, which is otherwise tolerably constant, is altered.—A. S.

Copper blast-furnace gases. Schorr. See X.

PATENTS.

Briquetting fine coal and the waste materials thereof; Apparatus and process for —. G. B. Damon, Glenside, Pa. U.S. Pats. 914,247 and 914,248, March 2, 1909.

THE fine coal or waste is first thoroughly dried and then the incombustible matter is separated. The dust is next removed by suitable machinery and the fine, dustless coal is briquetted. The separated portions are converted into gas in a producer and the gas is utilised to dry the coal and work the machinery.—W. H. C.

Coke ovens. H. W. Seymour, Leeds. Eng. Pat. 1409, July 21, 1908.

THE horizontal side heating flues are connected at either end, by vertical flues, with one or other of two horizontal flues situated beneath the sole of each oven. The opposite end of one horizontal sole-flue is connected with the left hand regenerator beneath the battery and the opposite end of the other sole-flue with the right hand regenerator. In one phase of the working, the air enters the regenerator on one side and passes thence through one of the sole-flues under each oven, to the vertical flue at one side, from which it is distributed to the air-inlet chambers, issuing therefrom to meet the gas for heating the flues. The waste gas passes from the opposite end of the flues into a similar set of air-chambers from which it is conducted by a vertical flue and the other sole-flue to the opposite regenerator. Dampers are provided by means of which the directions taken by the waste gas and air can be reversed.—W. H. C.

Coke-ovens. The Coke-Ovens and By-Products Co., Ltd., and S. N. Wellington, London. Eng. Pat. 6017, March 18, 1908.

THE claim is for an inclined coke-oven heated by producer gas generated in a furnace situated beneath the ovens on the charging side, each furnace serving for three or more ovens. The ovens have vertical heating flues and each oven has an inclined chequer-work regenerator directly beneath it. Each regenerator has an air heating flue on each side and a gas heating flue is arranged between each pair of air heating flues. The air and gas mix and enter at the base of alternate vertical flues, pass upwards, and

return down the next vertical flue to the regenerator. The vertical flues on each side of the oven are connected in pairs by an arched flue passing over the top of the oven. The gas is taken off by a series of vertical passages spaced apart in the top of each oven and connected by an external pipe which conducts the gas to the main.—W. H. C.

Coke-ovens; Regenerative — J. Mueller, Heme, Germany. Eng. Pat. 11,688, May 29, 1908. Under Int. Conv., May 29, 1907.

In a horizontal coke-oven each oven wall contains a series of vertical heating flues connected in pairs at their upper ends, and inlets for gas and hot air are provided at both ends of each flue. The odd-numbered flues receive gas and hot air at their lower ends, the combustion products pass through the connecting passages to the even-numbered flues and there receive a fresh supply of gas and hot air, and the combustion products finally pass to a sole-flue beneath one of the adjacent oven chambers leading to one of the regenerators. After reversing, the hot air from this regenerator is admitted along with gas at the bottom of the even-numbered heating flues, and the combustion products finally pass from the odd-numbered heating flues to a sole-flue beneath the other of the adjacent oven chambers, leading to the other regenerator. The hot air passes to the upper tuyères through passages in the walls separating adjacent heating flues. The tuyère bricks are formed with a central gas orifice surrounded by an annular air orifice, and the wall which separates the air and gas orifices is provided with four air passages inclined in the direction of the gas current and admitting air tangentially into the gas orifice to give the gas a rotary motion and so promote intimate mixing.—A. T. L.

Gas; Manufacture of — S. N. Wellington and A. S. Everest, London. Eng. Pat. 8186, April 13, 1908.

CARBON dioxide evolved by heating a "calcareous material" in a retort is mixed with superheated steam and passed through a retort containing carbon or coke and heated externally in a furnace. The carbon dioxide and the steam are decomposed by the incandescent carbon into carbon monoxide and hydrogen. The mixture (water-gas) is then passed through a carburettor for the purpose of enriching it with oil vapours.—W. H. C.

Gas-producers for use in melting, heating, etc., in the manufacture of steel. C. E. Scooby-Smith, Bolton, Lancs. Eng. Pat. 12,856, June 16, 1908.

THE gas-producer is provided with a rotatable hopper supported on rollers running in a water-trough formed in the top-plate of the producer. The hopper comprises a hopper-plate, provided with a water-trough for cooling, carrying a square casing which forms the body of the hopper and is provided with a sand-sealed cover. The hopper-valve or tongue is a rectangular plate hinged along one side of the casing and bearing, in its closed position, against the opposite side of the casing and also against adjustable sloping ledges of triangular cross-section fixed along the two other sides of the casing. A heavy poker with detachable prongs at its lower end passes through the hopper-plate and is suspended by a swivel link from an overhead horizontal girder which is free to rotate about the axis of the producer. The poker may be lowered on to the fuel and rotated by means of a "tommy-bar," and the hopper, hopper-plate, and poker may be rotated together about the axis of the producer between successive chargings.—A. T. L.

Gas-producer and process of generating gas. C. E. Lucke, New York. U.S. Pats. 914,663 and 915,034, March 9, 1909.

FUEL is fed in regulated quantities from the hopper, 10, on to the vibrating step-grate, 3, where the volatile constituents are gasified by a regulated stream of air introduced through the conduits, 21, 17. The incandescent non-volatile portion of the fuel is dropped on to the lower fuel bed supported on the grate, 25, where it is gasified by air introduced through the apertures, 31. The completely oxidised volatile constituents of the fuel

pass downwards through the lower incandescent fuel bed and escape along with the gases generated there through the gas pipe, 29, 28.—W. H. C.

Gas manufacture; Process for obtaining the by-products of —, with simultaneous purification of the gas. K. Burkheiser. Fr. Pat. 394,926, Oct. 5, 1908. Under Int. Conv., Oct. 14, 1907, and Feb. 11 and Sept. 14, 1908.

A PROCESS for obtaining ammonium sulphate and sulphite in the purification of crude coal-gas, coke-oven gas, and similar gases consists in passing the gas, previously freed from tar, over a heated oxidising substance such as bog-iron-ore, and causing the oxides of sulphur which are produced to combine with free ammonia. A part of the ammonia is present in the gas which passes over the oxidising substance, and a further quantity of ammonia is obtained by treating the liquor, collected in separating the tar, with slaked lime. This latter supply of ammonia is mixed with hot air or gas, and in one method of working is passed through the chamber containing iron oxide along with the crude gas containing sulphuretted hydrogen. In another method of working, the air or gas containing the ammonia obtained from the liquor, and the gases containing oxides of sulphur are passed alternately through a single washer, or these two currents of gas are passed continuously through separate washers through which the same liquid is circulated.—A. T. L.

Gases; Apparatus for purifying and cooling — H. Uhlmann. Ger. Pat. 207,169, Aug. 6, 1907.

THE apparatus is for the purification and cooling of gases intended for use in gas engines. It consists essentially of a chamber, open at the bottom, which dips into an outer receptacle containing water, and is provided with a depending partition movable vertically. At its lower end the partition carries an arched plate disposed horizontally. The outer receptacle has an overflow pipe for the cooling water, and the inner chamber is provided at the top with inlet pipes for the cooling water and the gas to be purified, and with a pipe leading to the gas-engine. During the suction stroke of the engine, a partial vacuum is produced in the space above the water in the inner receptacle, thus causing the water to rise to the level of the arched plate; the gas is forced to pass through the cooling water under the arched plate. On the completion of the suction stroke, the water level falls, rising again during the next suction stroke of the engine.—A. S.

Incandescence mantle; Metallic — for lighting and heating purposes. H. Reeser, London, and H. E. Bray, Woolwich. Eng. Pat. 13,828, June 30, 1908.

THE patent is for a mantle having its threads or filaments composed of an alloy of tungsten and molybdenum, or composed of a silver core coated with such an alloy. The alloy contains for ordinary purposes 80 per cent. of tungsten and 20 per cent. of molybdenum, but these

proportions may be varied according to the shade or intensity of the light required. The mantle may be of any of the usual forms, and its edge or edges are strengthened by holding them in a ring or bar of U section.

A. T. L.

Electric incandescent lamp filaments: Manufacture of —. The British Thomson-Houston Co., Ltd., London. From General Electric Co., Schenectady, U.S.A. Eng. Pat. 11,867, July 13, 1908.

ORDINARY metallised carbon filaments, made by flashing smooth "base filaments" in hydrocarbon vapour, and then firing the filaments packed in graphite in an electrically heated graphite tube, consist of a carbon core and a surrounding shell or skin which is not firmly fixed to the core, so that stripping or flaking may occur. The invention consists in roughening the "base filament" before flashing in order to lock the metallised shell or coating securely to the core, and so increase the life of the filament. The roughening is effected by heating the base filament in air by a momentary electric current, so that the resistance of the filament is increased by about 25 per cent. A. T. L.

Electrical glow lamps with metal filaments. T. McKenna, London. From Glühlampenwerk Anker, Ges.m.b.H., Berlin. Eng. Pat. 9,118, Sept. 11, 1908.

SUPPORTS for metal filaments in incandescence electric lamps are made of metal coated for about half its length by a special process with a low oxide of tantalum or of niobium. The support is first coated with colloidal tantalic or niobic acid, then slowly dried, and finally heated in a china tube to 1300° C. in an atmosphere of hydrogen. To obtain the tantalic or niobic acid in the colloidal form, a 5 per cent. solution of the potassium salt, obtained from the pure double fluoride of potassium and the rare metal by precipitating with ammonia and treating the precipitate with caustic potash, is poured into a 1 per cent. solution of sulphur dioxide. The colloidal acid is purified by dialysis and finally evaporated to a syrup.—A. T. L.

Coke ovens: Continuous heat-interchanging arrangement for —. E. Solvay, Brussels. U.S. Pat. 914,525, March 9, 1909.

SEE Eng. Pat. 16,786 of 1907; this J., 1908, 11. T. F. B.

Gas generators. J. Maly, Dresden, Saxony. Eng. Pat. 4529, Feb. 28, 1908.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, PETROLEUM, AND MINERAL WAXES.

PATENTS.

Benzene or its homologues: Producing — from petroleum. E. A. Starke, Berkeley, Cal. U.S. Pat. 913,780, March 2, 1909.

THE "distillate of petroleum which contains a benzene nucleus" is agitated and heated with concentrated sulphuric acid until the evolution of sulphur dioxide ceases. The mass is then allowed to settle until the sulphonic acids have separated from the petroleum and the benzene is recovered from the sulphonic acids by distillation.

—W. H. C.

Chlorinated compound and process of making same, and apparatus for utilising chlorine. J. W. Aylsworth, East Orange, N.J., Assignor to Fireproof Products Co., N.J. U.S. Pats. 914,223 and 914,224, March 2, 1908.

CHLORINE gas is forced through a suitable liquid organic substance, e.g., naphthalene, which is heated under pressure. An apparatus for effecting this consists of a closed chamber

containing the organic material and having inside it a series of inverted pan-shaped partitions. These partitions are arranged one above the other, the uppermost one being below the level of the liquid to be chlorinated. The chlorine gas is introduced into the chamber underneath the lowest partition, and, after flowing across it, then ascends to the second partition, and so on until it has reached the surface of the liquid. Another apparatus comprises a series of chlorinating chambers which are placed in communication with one another. Through these chambers the gas and the substance to be chlorinated are made to flow in opposite directions. Both forms of apparatus are provided with devices for separating and collecting the hydrochloric acid produced during the reaction.—P. F. C.

Chlorinating organic bodies: Process of —. C. Ellis, White Plains, N.Y., and K. P. McElroy, Washington, D.C., Assignors to Fireproof Products Co., New Jersey. U.S. Pat. 914,251, March 2, 1909.

CHLORINE, obtained by electrolysis of a suitable chloride, is caused to act upon a hydrocarbon of the aromatic series (e.g., naphthalene) in either the liquid or solid condition to obtain the desired organic chloride.—W. H. C.

Aromatic nitro-compounds: Process for preparing —. Chem. Fabr. Griman, Landshoff and Meyer, A.-G., Ger. Pat. 207,170, Feb. 2, 1908.

NITROGEN oxides diluted with air are absorbed by zinc oxide, copper oxide, or similar oxide of low basicity; the resulting product is heated in an iron tube to 290° C., when a mixture of air and benzene vapour is passed through the tube, the temperature being increased; formation of nitrobenzene begins at 300° C., but above 350° C. it is decomposed. The product consists of fairly pure mononitrobenzene, the yield being practically quantitative, as calculated from the nitrogen oxides used. When toluene is similarly treated, a mixture of about 11 per cent. of *m*- and 89 per cent. of *o*-nitrotoluene results.—T. F. B.

IV.—COLOURING MATTERS AND DYESTUFFS.

Safranin: Constitution of —. Studies in the azine series. Part I. J. T. Hewitt, S. H. Newman, and T. F. Winnill. Chem. Soc. Proc., 1909, 26, 86.

PHENOSAFRANINE has the composition of a salt (chloride) of phenylphenazonium. According to Bernthsen the two amino-groups are symmetrically situated, whilst Witt supposed that one was in the phenyl group, only one being attached to the phenazine nucleus. The question was apparently decided in favour of Bernthsen's formula by Körner and Schraube, who obtained identical dialkylsafranines by the oxidation of (a) one molecule of *as*-dialkyl-*p*-phenylenediamine with two molecules of aniline, and (b) one molecule each of *p*-phenylenediamine, aniline, and its dialkyl derivative. More recently, P. Barbier and P. Sisley (Ann. Chim. Phys., 1908 (viii.), 13, 96, and this J., 1908, 17) have stated that phenosafranin, as prepared by oxidising *p*-phenylenediamine with aniline, consists essentially of the asymmetric compound mixed with small amounts of an isomeride having the structure given by Bernthsen. The present authors find that the hydroxyaphosafranone obtained from safranin is identical with that prepared by Jaubert's method from nitrosophenol and *m*-hydroxydiphenylamine (Ber., 1895, 28, 273), since the acetyl derivatives prepared from both specimens melt at 271° (uncorr.) whether alone or mixed (Fischer and Hepp give 265–268°. Ber., 1897, 30, 101).

The synthesis of an asymmetric phenosafranin by oxidation of aniline with 2:4'-diaminodiphenylamine described by Barbier and Sisley (*loc. cit.*, p. 102) could not be realised, any safranin obtained by them probably owing its origin to admixed 4:4'-diaminodiphenylamine, since potassium bichromate converts 2:4'-diaminodiphenylamine into aminophenazine whether aniline be present or not.

The experiments recorded are only compatible with the symmetrical (Bernthsen's) formula for phenosafranin.

Flavonol derivatives; Remarks on Herzig and Hofmann's paper on completely methylated — N. Walschko. Ber., 1909, 42, 726—728.

THE author points out that Herzig and Hofmann's method of preparing pentamethylquercetin (Ber., 1909, 42, 155) by treating quercetin with a large excess of alkali and dimethyl sulphate whereby a yield of 25 per cent. of the theoretical was obtained is not so suitable as his own which was published in 1904. Trimethylquercetin is prepared by dissolving 4 grms. of quercetin in 200 c.c. of hot methyl alcohol, adding to the partly cooled solution 8 grms. of dimethyl sulphate and then, gradually, 3.6 grms. of potassium hydroxide dissolved in a little alcohol. The reddish-brown liquid soon resumes its original yellow colour and then the same quantities of dimethyl sulphate and potassium hydroxide are added and the whole left overnight. The resulting crystalline precipitate is washed with water and recrystallised from alcohol, whereby rather more than 50 per cent. of the theoretical yield of trimethylquercetin is obtained. Pentamethylquercetin is prepared by triturating the potassium salt of trimethylquercetin with an excess of dimethyl sulphate and, after standing overnight, treating with water and recrystallising the residue from methyl alcohol. The yield is quantitative. —J. C. C.

Dyestuff of the antique purple from Murex brandaris. P. Friedlaender. Ber., 1909, 42, 765—770.

THE author has continued the investigation of this dyestuff (this J., 1907, 1003) and finds it to consist of 6:6'-dibromo-indigo.

Its identity was proved by a comparison with the synthetic dyestuff prepared as follows: *p*-Bromo-*o*-toluidine is converted into 4-bromo-2-aminobenzoic acid; this, when treated with chloroacetic acid furnishes bromophenylglycine-*o*-carboxylic acid, which is condensed with acetic anhydride and sodium acetate to acetyl bromoindoxyl. Both the natural and the synthetic dyestuff give a pale yellow vat from which cotton is dyed in fast, reddish-violet shades. —J. C. C.

Indigoid dyestuffs as oil colours. Eibner. See XIII.4.

PATENTS.

Vat-dyestuffs; Manufacture of new sulphurised — of the anthraquinone series. O. Imray, London. From Soc. of Chem. Ind. in Basle, Switzerland. Eng. Pat. 20,094, Sept. 24, 1908.

By heating 2-methylbenzanthrone with sulphur or alkali polysulphides, dyestuffs are obtained which dye unmordanted cotton in an alkaline hydrosulphite vat, in blue-green to green-black shades of good fastness to washing, light, and chlorine. By heating 10 parts of methylbenzanthrone with 50 parts of sulphur at 200—240° C., until the evolution of hydrogen sulphide ceases, a product is obtained which when purified forms a black powder, dissolves in alkaline hydrosulphite yielding an olive-coloured vat, and dyes cotton in blue-green shades. The dyestuff obtained by heating 10 parts of methylbenzanthrone with 40—50 parts of sulphur at 300—330° C., yields an olive-coloured vat in which cotton is dyed a deep black. When heated with sodium tetrasulphide for 1 hour at 200—240° C., methylbenzanthrone yields a dyestuff which gives a blue vat in which cotton is dyed in green-blue shades. —F. M.

**o*-Hydroxyazo dyestuffs; Process for preparing chrome* —. Basler Chem. Fabr. Ger. Pat. 206,698, July 27, 1907.

THE diazo derivative of 1-amino-2-naphthol-3-carboxylic acid or of its mono-nitro derivative is combined with resorcinol, naphthols or their sulphonic acids, or other suitable components for *o*-hydroxyazo dyestuffs. According to the component used, a wide range of shades is obtainable after chroming. —T. F. B.

Indoxylcarboxylic acid and indoxyl; Process for preparing —. Kalle und Co., A.-G. Ger. Pat. 206,903, Feb. 6, 1908.

o-NITROPHENYLCYANIDE is reduced by iron and acetic or hydrochloric acid to *o*-aminophenylexamide; chloroacetic acid converts this into *o*-cyanophenylglycine, which is readily converted into indoxyl or indoxylcarboxylic acid by heating with aqueous solutions of alkali hydroxides. —T. F. B.

Indigoid dyestuffs; Process for preparing —. Kalle und Co., Akt.-Ges. Ger. Pat. 207,097, Jan. 9, 1908.

DYESTUFFS which resemble indigo, giving red-violet, deep blue, and deep green dyeings from the vat, are obtained by the condensation of α -isatin derivatives (e.g., α -isatin chloride or anilide, thioisatin, α -methylisatin) with substituted phenols or naphthols, which have at least one *o*-position to the hydroxyl group free. For example, 17.4 kilos, of 1:4-dihydroxynaphthalenemonomethyl ether, 22 kilos, of α -isatin anilide, and 50 kilos, of acetic anhydride or 120 kilos, of benzene are heated under a reflux condenser. The dyestuff crystallises on cooling, and dyes wool fast blue shades from the vat. These dyestuffs are fast to alkalis, whereas those from α -isatin derivatives and unsubstituted phenols or naphthols are not. —T. F. B.

Dyestuff [from dinitrosorcinol]; Process for preparing a brown —. K. Sunder. Ger. Pat. 207,465, Sept. 11, 1907.

RESORCINOL (100 parts) is nitrated, and the dinitro-compound obtained is made into a paste with water, and stirred for some time with 20 per cent. ammonia solution (1000 parts), at the ordinary temperature; at first a brown solution is produced, but gradually a green, crystalline compound is precipitated, which is filtered off, washed with a solution of salt, and dried. It contains no free ammonia, and is soluble in cold water, and readily in warm water. When its aqueous solutions are suitably thickened and printed on fabrics, even without mordants, and then steamed, brown shades very fast to soaping and light are produced. It can also be applied in conjunction with various acid and basic dyestuffs, with or without a mordant. —T. F. B.

Colouring matters containing sulphur [Thioindigo dyestuffs] and capable of dyeing from a vat; Manufacture of red —. P. A. Newton, London. From Farbenfabr. vorm. F. Bayer und Co., Elberfeld, Germany. Eng. Pat. 10,755, May 18, 1908.

V.—PREPARING, BLEACHING, DYEING, PRINTING, AND FINISHING TEXTILES YARNS, AND FIBRES.

Silk; Determination of weighting in —. P. Heermann. Färber-Zeit., 1909, 20, 75—78.

MOST recent processes for the estimation of weighting in silk fabrics depend upon the extraction of the weighting substance. In spite of the success of many of these methods, especially that of Ristenpart for Monopol Blacks (this J., 1908, 329), much can still be said for the estimation by nitrogen determination. Sisley, by his investigations (this J., 1907, 605) proved that extraction methods only

gave uniform results under certain definite conditions and that slight variations from these conditions led to quite different results being obtained. The author finds that soft, slightly weighted or tender silks give erroneous results by extraction methods on account of the action on the material of the reagents employed. This is especially true of the alkali-treatment in Ristenpart's method. By substituting for the $N/1$ -potassium hydroxide used in this method, a mixture of equal parts of $N/1$ potassium hydroxide and glycerin of 28° B., this action on the fibre is very considerably reduced. On applying this modification of Ristenpart's method to silks weighted with iron compounds, it was found that the alkali-glycerin solution dissolves Prussian blue quantitatively from the fibre if the extraction is effected at 80° C., and from the solution obtained, the Prussian blue can be precipitated by acidification. Any iron present as oxide or gallate remains of course on the fibre. If a silk be heavily weighted with say tin oxide and tin phosphate in addition to Prussian blue, it is necessary, after once extracting with the alkali-glycerin solution, to treat the material with cold hydrochloric acid (20 per cent.), and finally to repeat the extraction. By this means the tin phosphate is removed by the acid, and the Prussian blue by the alkali-glycerin solution, whilst the tin oxide remains on the fibre.—P. F. C.

Treating cellulose. Berl. See XIX.

Electrolytic bleaching. Fraass. See XIX.

PATENTS.

Cellulose and albuminoids [artificial silk]; Process for strengthening materials composed of —. X. Eschaler, Second and Third Additions, dated Oct. 7, 1908, to Fr. Pat. 374,724, April 24, 1906. (See this J., 1907, 821; 1908, 157.)

THE aldehyde and the dehydrating agent which are employed for strengthening artificial silk may be applied to the material either alternately or simultaneously. The following process gives good results. The material to be treated is impregnated with a solution of lactic acid and alum, of such a concentration that the fibre retains 5–6 per cent. of its weight of each reagent. It is then placed in a closed vessel containing a dehydrating agent such as sulphuric acid at 50–60° C. Through an opening in the wall of the vessel, 10–25 parts of a 40 per cent. solution of formaldehyde are introduced for each 100 parts of material. The opening is then sealed and the apparatus is heated to 50–60° C. for a further 5 or 6 hours. The material is then removed, washed, and dried. Fibres which have been treated in the manner described in this patent, exhibit an increased affinity for dyestuffs if treated with a solution of sodium or potassium hydroxide. If a concentrated solution be employed, the time of action must be short or the strength of the fibre will be affected and its length will be diminished. Oxidising agents such as hypochlorites may be added to the solution.—P. F. C.

Cellulose products [fibres, etc.] from cellulose-cuprammonium solutions; Process for preparing —. P. Friedrich, Ger. Pat. 206,883, Aug. 27, 1907.

SOLUTIONS of cellulose in ammoniacal copper solutions, containing 6 per cent. of cellulose, are forced through suitable orifices into a coagulating bath consisting of 25 kilos. of sodium chloride and 4.5 kilos. of sodium hydroxide in 100 litres of water, preferably warmed. The threads are washed in the usual manner and dried under tension.

—T. F. B.

Textile and other materials; Treatment by liquid processes of —. G. Malard, Tourecoing, France. Eng. Pat. 759, Jan. 13, 1908.

THE invention is described as applied to an apparatus for scouring and degreasing wool. The wool is carried on an endless band above a vat divided into compartments. Fresh scouring liquor is introduced into a compartment at one end, and the liquor charged with wool grease is withdrawn from the last compartment at the other end. The object of the invention is to provide means for transferring a portion of the liquor from one compartment to the

next in a direction opposite to that in which the wool travels. From each compartment the liquor is forced by a pump or the like through an ascending pipe ending in a sprinkler, through which it is discharged on to the wool. In each compartment also is a float, the one in the first compartment being connected to the tap controlling the pipe through which fresh liquor is supplied. The other floats are connected to oscillating trays above the compartments and directly below the sprinklers, and these work in such a manner that of the liquor withdrawn from a given compartment and forced through the sprinkler, the first portion which drains through the wool and which is hence most highly charged with wool grease, flows from the oscillating tray into the next compartment nearer the outlet end, and then as the float in this compartment rises, the tray is gradually tilted in the opposite direction, and the latter portion of the liquor flows back into the compartment from which it was withdrawn.

—A. S.

Wool-scouring and other liquors; Apparatus for burning the evil-smelling distillation gases produced in working-up —. O. Zahn. Ger. Pat. 206,747, April 16, 1907.

THE gases are passed through a combustion chamber in which fuel gas is burnt with the least possible quantity of air. Separate inlets, fitted with dampers, are provided for supplying air for the combustion of the fuel gas and of the distillation gases respectively. The inlet for the air for burning the distillation gases is disposed above the other air inlet, so that the air is preheated by passing through the fuel gas flame.—A. S.

Chlorine gas [for bleaching]; Method of treating and utilising —. E. C. Paramore, Philadelphia, Pa., Assignor to Electro-Bleaching Gas Co., New York. U.S. Pat. 908,126, Dec. 29, 1908.

CHLORINE gas is dried, cooled say to 0° C., then suddenly heated by passing it through a porcelain tube heated, for example, to 500° F., next electrified, and afterwards again cooled and liquefied. The electrification of the gas is effected by passing it through an annular glass chamber surrounding an iron core on which is wound a primary coil connected to a source of electric current of an "extremely high-tensioned oscillatory character"; the glass chamber itself is wound with a secondary coil of fine wire, which acts in a similar manner to the step-up coil of a transformer. It is stated that after this treatment the chlorine gas has little or no odour, whilst its bleaching properties are improved. (See also Eng. Pat. 2039 of 1901 and U.S. Pat. 786,595 of 1905; this J., 1901, 1002; 1905, 503.)—A. S.

Washing and bleaching liquid; Process for the preparation of a —. M. Vogtherr and H. Knorr. Ger. Pat. 207,258, Jan. 11, 1908.

A WASHING and bleaching liquid, which has no injurious action on the fibre, is prepared by leading chlorine into a solution of sodium carbonate until evolution of carbon dioxide begins, then adding caustic soda, and finally leading in carbon dioxide, until the liquor contains only sodium bicarbonate in addition to sodium hypochlorite and sodium chloride.—A. S.

Dyeing machine. R. P. Smith and G. E. Drum, Philadelphia, Pa. U.S. Pat. 905,473, Dec. 1, 1908.

THE material to be dyed is placed in a rectangular cage, which is divided into compartments by means of perforated, hinged partition walls. The top and bottom of the cage are also perforated, and the side walls project a little beyond them so that when the receptacle is lowered into the dye-vat, these extensions engage in grooves and the circulating dye-liquor is forced to pass through the cage, which fits over a perforated false bottom in the dye-vat. The space below this false bottom is in communication with two cylindrical chambers fixed to the side of the vessel and the upper parts of these are in communication with channels in the perforated cover of the machine. Screw propellers work inside the cylinders and circulate the dye-liquor, forcing it up through the material or over the cover of the dye-vat which distributes

it evenly over the material. Upon completion of the dyeing operation, the cage is lifted out of the dye-vat.

—F. M.

Textile materials; Apparatus for the boiling, dyeing, impregnation, etc., of —. F. F. Gebauer. Ger. Pat. 206,708, June 15, 1907.

IN apparatus of the type in which the liquor is circulated continuously through the system, a high-pressure turbine-pump is inserted in the circuit, and suitable connections and valves are provided, whereby this pump first sets in action a water-jet pump in order to produce a vacuum in the receptacle in which the treatment of the textile material is performed, then causes the liquor to circulate through the system, and finally when the treatment is completed, causes cold water to pass through the apparatus.

—A. S.

Crape-like effects on cotton tissues; Process for the production of —. C. Schimmel, jun. Ger. Pat. 207,372, May 14, 1907.

IN the production of crape-like effects on cotton tissues by spraying them with hot water, the effect produced depends upon the temperature of the water. According to the present patent, a suitable substance, e.g., calcium chlorate, is added to the water in order to allow of its being used at a higher temperature than hitherto.—A. S.

Fireproof material [fibre]. J. W. Aylsworth, East Orange, N.J., Assignor to Fireproof Products Co., N.J. U.S. Pat. 914,222, March 2, 1909.

THE fibre is impregnated with a chlorinated derivative of naphthalene (see U.S. Pat. 914,223, page 360.), which contains about 68 per cent. of chlorine, is soluble in chloroform, carbon tetrachloride, and naphtha, has a sp. gr. about 1.85, m. pt. 262° F., and is waxlike in appearance.—P. F. C.

VI.—COLOURING WOOD, PAPER, LEATHER, &c.

PATENT.

Wood; Colouring —. W. A. Hall, New York, Assignor to American Mahogany Co., Maine. U.S. Pat. 913,128, Feb. 23, 1909.

THE wood is first subjected to the action of a vacuum in order to remove the air and render the wood absorbent, and it is then treated, under high pressure, with a hot aqueous ammoniacal solution, containing a suitable colouring matter which dissolves in, but is not injured by, an ammonia solution.—B. N.

VII.—ACIDS, ALKALIS, SALTS, AND NON-METALLIC ELEMENTS.

Caro's acid (monosulpho per-acid); Synthesis and formula of —. H. Ahrlé. J. prakt. Chem., 1909, 79, 129—164. (See this J., 1909, 172, 278, 671, 777; 1901, 578; 1902, 343, 913.)

THE author first discusses the literature and shows that upon theoretical grounds the most probable formula for Caro's acid is $\text{SO}_3\text{H}\cdot\text{O}\cdot\text{OH}$. (The $\text{O}\cdot\text{OH}$ group is

written as shown in order to avoid discussion of the nature of the linking of the O_2 group in peroxides.) A study of the kinetics of the reaction between hydrogen peroxide and sulphuric acid confirmed this view. The formation of Caro's acid (monosulpho per-acid) in this way may thus be expressed by the equation: $\text{H}_2\text{O}_2 + \text{H}_2\text{SO}_4 = \text{H}_2\text{SO}_3 + \text{H}_2\text{O}$. Attempts were also made to prepare the acid synthetically from anhydrous hydrogen peroxide (see this J., 1902, 986) and sulphur trioxide, and small quantities of the acid of a concentration as high as 92 per cent. were obtained in this way. In one or two cases crystals of the acid were produced which began to melt far below 0°C . The high percentage Caro's acid is a tolerably mobile liquid at the ordinary temperature and rapidly decomposes. In presence of bright platinum, or of the finely-divided metal, or of powdered manganese dioxide, or finely-divided silver, decomposition occurs with explosive violence. Lead dust, zinc dust, magnesium powder, and wood charcoal have no noteworthy effect on the decomposition. Iron dust alone is also without appreciable effect, but in presence of a trace of manganese dioxide, causes a vigorous reaction. Wool and cellulose are carbonised nearly instantaneously by the acid. If a drop of the acid be placed on cotton, no action is observed at first, but after a few seconds a pale yellow flame is produced and the cotton takes fire.—A. S.

Magnesite; Analysis of —. Determination of small quantities of calcium in the presence of much magnesian. F. Hundeshagen. Z. öffentl. Chem., 1909, 15, 85—93.

ONE gm. of the powdered magnesite is boiled with 80 c.c. of 5 per cent. hydrochloric acid for 15 minutes, and the solution is filtered; the filtrate is evaporated to dryness, and the residue is dissolved in 30 c.c. of warm water containing 4 grms. of sodium sulphate. Forty c.c. of 90 per cent. alcohol are then added, with constant stirring, and the mixture is set aside at a temperature of from 17.5° to 20°C . for 5 hours, when the crystalline precipitate of calcium sulphate is collected on a filter, washed with 50 per cent. alcohol, dissolved in hot dilute hydrochloric acid, and the calcium then determined in the usual way as oxalate, after precipitation of the small quantity of iron oxide which is thrown down with the calcium sulphate. The dilute alcoholic filtrate containing the magnesium salts is evaporated to remove the alcohol, and the iron and magnesium determined in the residual solution as usual. Having ascertained the quantity of calcium present as described above, another portion of the magnesite may be dissolved, and the calcium and magnesium precipitated together as phosphates after removal of iron and aluminium; the precipitate is collected on a filter, ignited, and weighed, and the amount of calcium phosphate deducted in order to obtain the quantity of magnesium. The magnesium and calcium may also be determined together by titration, using methyl orange as indicator; for this purpose the magnesite is dissolved in a known excess of standard sulphuric acid and the excess titrated back with standard sodium carbonate solution. After subtracting the alkalinity due to calcium, the difference represents the magnesium present in the form of oxide, hydroxide, and carbonate. The hydroxide is determined by taking the loss on heating the dry sample to a temperature of 300° — 350°C ., and the carbonate by further heating the sample to redness. On deducting the quantity of magnesium hydroxide and carbonate, the actual amount of magnesium oxide in the sample is obtained.—W. P. S.

Chlorates; Detection and colorimetric determination of —. J. F. Virgili. Ann. Chim. analyt., 1909, 14, 85—91.

WHEN about 1 c.c. of a solution of a chlorate, or about 1 gm. of the salt, is treated with 4 c.c. of a 5 per cent. solution of aniline hydrochloride in hydrochloric acid of sp. gr. 1.12, a violet coloration is produced immediately; the colour rapidly turns blue and, after some time, fades, a greenish-blue precipitate being formed. If hydrochloric acid of sp. gr. 1.45 be employed in preparing the reagent, the colorations produced are more intense, but more fugitive. By means of the test as little as 0.00002 gm. of a chlorate can be detected with certainty, but other

substances, such as chlorine, hypochlorites, hypobromites, bromates, iodates, hydrogen peroxide, peroxides, chromates, bichromates, permanganates, vanadates, and ferricyanides also give the reaction. As the coloration, in the case of pure chlorates, is proportional to the amount of the salt present, the quantity of chlorate in an unknown solution may be ascertained by comparing, after 25 minutes, the coloration obtained with that produced by known quantities of chlorate. It is essential that exactly the same proportion of aqueous solution to reagent be used both in the test solution and in the standards.—W. P. S.

Reducing action of electrolytic hydrogen on arsenious and arsenic acids when liberated from the surface of different elements. W. Thomson. Proc. Roy. Soc. Edinburgh, 1908—1909, 29, II., 84—95.

Using the apparatus described previously (this J., 1904, 790), the author has determined the velocity with which arseniuretted hydrogen is evolved at different cathodes from solutions of arsenious acid and arsenic acid respectively. With this apparatus, 0.0000005413 grm. of arsenic can be detected, and this quantity was taken as a "unit." In each experiment, 5 c.c. of a solution containing 50 "units" of arsenic and diluted to 30 c.c. with dilute sulphuric acid (1:6 by vol.) were used. It was found that the current density employed had little influence on the results. With a current of 3 amperes the following results were obtained, which show that Chapman and Law's suggestion that the reducing efficiency of hydrogen depends largely upon the supertension of the cathode at which it is liberated (see this J., 1906, 137) does not hold good.

Relative amounts of arsenic removed as arseniuretted hydrogen from (a) arsenious acid and (b) arsenic acid from 100 parts introduced, in 25 minutes.

Cathode.	(a) Arsenious acid.	(b) Arsenic acid.	Supertension (volts).
Lead	100	98.5	0.64
Zinc	100	41	0.70
Cadmium	100	27	0.48
Tin	100	18.5	0.53
Silver	100	0	0.15
Graphite	100	4	—
Iron	93	40.5	0.08
Platinum	88.5	0	0.09
Aluminium	82	0	—
Gold	74	4	0.02
Cobalt	43.5	0	—
Nickel	42.5	0	0.21
Palladium	38	0	0.46

The cathodes in the table are arranged in the order in which they are capable of removing arsenic as arseniuretted hydrogen from a solution of arsenious acid.

A study of the velocities with which arseniuretted hydrogen was liberated in successive periods of 2½ mins., showed that the reduction of arsenious acid with lead, zinc, cadmium, tin, and silver cathodes, is practically a unimolecular reaction.—A. S.

Calcium phosphide; Manufacture of amorphous —. C. E. Munroe. J. Ind. and Eng. Chem., 1909, 1, 178—181.

The phosphide was prepared in crucibles made from wrought iron pipes welded at one end, 7 in. long outside and 6 in. inside; outside diameter, 5½ in.; inside, 5 in. The crucibles were provided with grooved lids, ¼ in. thick and 6 in. outside diameter, fitted with asbestos gaskets, and the lids were held in place by wedge-shaped keys which passed through slotted lugs welded on the sides of the crucibles. A wrought iron feed pipe, 12 in. long and 1 in. diameter, passed through the lid, and was fitted outside the crucible with a wrought-iron cap. Each crucible was charged with 1400 grms. of burnt lime in lumps 1—1½ in. diameter, the cover was fastened on, and the whole placed in an ordinary crucible furnace and heated to between a dark and cherry redness. 200 grms. of phosphorus were then introduced through the feed pipe and the cap immediately replaced. When fuming ceased, the crucible was removed from the furnace. The cost of

the phosphide thus produced, including labour and materials, was 20 cents (10d.) per lb., and the same pots were used for 8 years without repairs. The phosphide was very active, yielding immediately a spontaneously inflammable gas on contact with water. It is suitable for use as an attachment to life-belts, and also to torpedoes for the purpose of locating them after they have sunk; and when mixed with calcium carbide is useful in other ways in naval warfare.—A. S.

Metatungstates; Nature of — and existence of rotatory power in crystals of potassium metatungstate. H. Copaux. Compt. rend., 1909, 148, 633—636.

The author considers that the generally accepted formula for the alkali metatungstates, *viz.* $(4WO_3)_2M_2O + aq.$, gives a very imperfect idea of the nature of these compounds, and that the formula $(3H_2O, 24WO_3, 6M_2O + aq.)$ is more rational. Barium metatungstate (ordinary formula $(4WO_3)BaO + 9.5H_2O$) and borotungstate are completely isomorphous; this isomorphism is accounted for if the formula, $(3H_2O, 24WO_3, 6BaO + 54H_2O)$, is assigned to the metatungstate, since the author has previously shown that the borotungstate has the formula $B_2O_3, 24WO_3, 5BaO + 54H_2O$. The objection that these salts differ, in that one contains six, whilst the other contains only five BaO -groups, is met in the following way: When crystallised at a low temperature, potassium metatungstate forms quadratic octahedra, $(4WO_3)_2K_2O + 8H_2O$. At a slightly higher temperature, hexagonal prisms, $(4WO_3)_2K_2O + 6.5H_2O$, are obtained; these crystals are not only completely isomorphous with those of potassium boro- and silicotungstate, but like the latter, they are optically active and all dextro-rotatory. The formula $3H_2O, 24WO_3, 6K_2O + 36H_2O$ is therefore assigned to this metatungstate, those of potassium boro- and silico-tungstate being $B_2O_3, 24WO_3, 5K_2O + 36H_2O$, and $Si_2O_5, 24WO_3, 4K_2O + 36H_2O$. The analogy between these formulae is also in accordance with the fact that the metatungstates and the complex tungstates have certain general properties in common. These compounds constitute a series represented as follows:—

Metatungstates, $3H_2O, 24WO_3, 6M_2O + aq.$
 Borotungstates, $B_2O_3, 24WO_3, 5M_2O + aq.$
 Silicotungstates, $Si_2O_5, 24WO_3, 4M_2O + aq.$
 Phosphotungstates, $P_2O_5, 24WO_3, 3M_2O + aq.$

—L. E.

Pyrosulphuryl chloride. W. Prandtl and P. Borinski. Z. anorg. Chem., 1909, 62, 24—33.

THE physical constants and chemical characters of pyrosulphuryl chloride as given by different observers differ so widely as to suggest that the pure substance has not always been obtained. The authors' investigations show that this is the case, and that all who have worked with the substance, except Konowaloff, have really had in their hands a mixture of pyrosulphuryl chloride and sulphuryl hydroxychloride. They find that the best method of preparation is to react with sulphur trioxide on carbon tetrachloride. The least trace of moisture produces some sulphuryl hydroxychloride; and fractional distillation of the product separates it into pure pyrosulphuryl chloride, boiling at $150^\circ C.$, and a mixture, $SO_2(OH)Cl + 2$ or $3S_2O_5Cl_2$, boiling at about $137^\circ C.$ If the latter be treated with cold water, the sulphuryl hydroxychloride is decomposed, and on separating the liquids, and drying and distilling the denser layer, an additional quantity of pyrosulphuryl chloride is obtained. This is a clear, colourless, mobile liquid, very slightly fuming in moist air, of sp. gr. 1.876 at $0^\circ C.$, 1.844 at $18^\circ C.$, and boiling at $150.7^\circ C.$ under a pressure of 730.5 mm. Its vapour density is 7.27 (calculated 7.43). It is very slowly decomposed by water ($S_2O_5Cl_2 + 3H_2O = 2H_2SO_4 + 2HCl$), whilst sulphuryl hydroxychloride is decomposed rapidly and violently; and it gives, unlike sulphuryl hydroxychloride, no coloration with selenium or tellurium.—J. T. D.

Silicon, amorphous; Action of hydrochloric acid gas on —. A. Bosson and L. Fournier. Compt. rend., 1909, 148, 555—557.

THOUGH graphite or crystalline silicon, heated in a stream of hydrochloric acid, yields only silicon tetrachloride and

silicon chloroform, amorphous silicon, when similarly treated, is acted on at a lower temperature, and yields the compounds, SiH_2Cl_2 and SiH_3Cl . These are colourless liquids, boiling at 12°C . and -10°C . respectively; very mobile, having high coefficients of thermal expansion, readily decomposed by water or alkalis with evolution of hydrogen, and forming explosive mixtures with air. They are very difficult to condense from the excess of hydrochloric acid gas and the hydrogen which accompany them at their formation.—J. T. D.

PATENTS.

Nitrous vapours: Process for the absorption of —. Norsk Hydro-Elektrisk Kvaelfstofkieselskab, Ger. Pat. 206,949, Nov. 20, 1907.

NITROUS fumes, such as are obtained, for instance, by the electrical oxidation of atmospheric nitrogen, are absorbed by means of a metallic cyanamide, preferably calcium cyanamide, a mixture of ammonium nitrate and a metallic nitrate (calcium nitrate), valuable as a fertiliser, being produced. It is stated that the nitrous fumes are absorbed readily and completely by calcium cyanamide.—A. S.

Nitrogen oxides: Apparatus for moving and conveying hot —. W. Ostwald, Ger. Pat. 207,154, Nov. 13, 1906.

NICKEL-STEEL is not attacked by hot gaseous nitrogen oxides, and elaim is made for the use of this alloy for all parts of apparatus which come in contact with such hot gases. Care must be taken to prevent any condensation of the nitrous gases.—A. S.

Nitric acid from calcium nitrate: Process for the preparation of —. Chem. Werke vorm. Dr. H. Byk, Ger. Pat. 208,134, Oct. 6, 1907.

CALCIUM nitrate or a solution of calcium nitrate in concentrated nitric acid is treated with the requisite quantity of concentrated sulphuric acid, and the nitric acid formed is separated from the calcium sulphate by filtering and pressing, or by means of a centrifugal machine.—A. S.

Separation of gases of different densities, more particularly intended for increasing the proportion of oxygen in atmospheric air. A. Tavernier, Puteaux, France, Eng. Pat. 2029, Jan. 29, 1908.

THE air is compressed and cooled by being passed through a coil or other cooling device and then passed through an ozonising apparatus to increase the difference in density between the oxygen and the nitrogen. From the ozoniser the air, still under pressure, enters a turbine driven by an electric motor where the gases of different densities are separated by centrifugal force. The denser gas escapes from the periphery and the lighter gas from the axis of the turbine into two separate vessels from which the separated gases can only escape when the pressure is sufficient to open the spring-controlled outlet valves.—W. H. C.

Hydrogen: Composition of matter for generating —. G. F. Brindley, Niagara Falls, Canada, Assignor to The Roessler and Hasslacher Chem. Co., New York, U.S. Pat. 909,536, Jan. 12, 1909.

AN alkali or alkaline-earth metal, for example sodium, in a finely-divided state, is mixed with a crude hydrocarbon oil or similar substance which will temporarily prevent oxidation of the metal, and with an inert substance such as infusorial earth, and the mixture is compressed into tablets or briquettes, which when brought into contact with water, will generate hydrogen. In order to increase the yield of hydrogen, a metal (aluminium, silicon) which forms a hydroxide, the hydrogen of which can be replaced by an alkali or alkaline-earth metal, is also incorporated in the mixture.—A. S.

Silicon carbide: Manufacture of —. F. J. Tone, Assignor to The Carborundum Co., Niagara Falls, N.Y., U.S. Pat. 913,324, Feb. 23, 1909.

THE claim is for dense, compact silicon carbide, prepared

by heating a mass of porous carbide in proximity to "commingled vapours of substances containing carbon and silicon" to a temperature sufficient to cause the carbon and silicon to combine throughout the pores of the silicon carbide mass.—O. R.

Calcium oxalate: Manufacture of —. W. A. Dyes, Manchester, From A. Hempel, Leipzig-Plagwitz, Germany, Eng. Pat. 3302, Feb. 21, 1908.

AN alkali formate is heated with slaked lime or a calcium salt, either at ordinary pressure at a temperature of about 360° to 420°C . or under pressure at the same range of temperatures (with consequent acceleration of the reaction), or under diminished pressure at 240° to 300°C . Calcium oxalate and caustic alkali are formed and the latter is removed by boiling with water, preferably under pressure.—O. R.

Oxalic acid: Manufacture of —. W. A. Dyes, Manchester, From A. Hempel, Leipzig-Plagwitz, Germany, Eng. Pat. 3304, Feb. 21, 1908.

ACIDS or acid salts of strong acids are added in small portions to oxalates of alkali or alkaline-earth metals, heated to about 100°C . under diminished pressure, and oxalic acid is sublimed into a receiver.—O. R.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

Impregnated timber used for mines; Properties (especially strength) of —. D. Stens. Gluckauf, 1909, 45, 317—323.

THE author has compared the strengths of a number of samples of mine timber, impregnated by various processes, with that of non-impregnated timber. The results are not regarded as final, but the general conclusion is drawn that impregnation, excepting with tar oils, reduces the strength of timber, especially where a high temperature is used in the process of impregnating. Tar oils however make the wood very inflammable, volumes of dense black smoke being evolved during burning; whereas impregnation by solutions of salts, as a rule, has the effect of making the wood difficult to burn.—F. SONS.

Calcium aluminate; Effect of — on mortars (and natural cements). H. S. Spackman. J. Franklin Inst., 1909, 167, 186—204.

CALCIUM ALUMINATE was found to have a decided accelerating effect on the setting time and to increase the ultimate strength of lime mortars and natural cements. Clay and shale, which were devoid of binding properties when used by themselves, developed cementitious and hydraulic properties when mixed with calcium aluminate. Practically any desired setting time could be obtained by proportioning the amounts of calcium aluminate, used as accelerator, and of calcium sulphate, used as retarding agent. The strength of mortars made with such mixtures could be increased above the strength of Portland cement at the earlier periods of setting, by using a sufficient quantity of the accelerator. The addition of small proportions of calcium aluminate to hydrated lime alone, gave valuable wall-plaster compositions having quick hardening and increased spreading properties. Larger proportions of aluminate gave strongly hydraulic compositions of great strength. The author publishes the results of a large number of tests made with mortars containing calcium aluminate, of which the most striking is a comparison of the tensile strengths of two series of natural cement mortars at various periods. The one series, (a), had as basis, natural cement containing 10 per cent. of added aluminate, and the other, (b), untreated cement. The tensile strengths in lb. per sq. in. after 24 hours, 7 days, 28 days, and 3 months respectively were: for (a), 155, 229, 329, and 437; and for (b), 43, 88, 173, and 237 respectively. The author concludes that judicious mixtures of natural cement clinker, with calcium aluminate and calcium sulphate may yield slow-setting and quick-hardening cements, which, by reason of their low cost and ease of manufacture may compete seriously with Portland cement.—O. R.

Cement; Recrystallisation and formation of colloids during the setting of —. H. Ambrom. Tonind.-Zeit., 1909, 33, 270—272.

THE behaviour of cement during setting was studied under the microscope. The cement was placed as a very thin layer on slides, which were moistened, covered as usual, and kept under bell-jars containing water to prevent drying of the cement. During the first few days, the individual particles of the cement were seen to become surrounded by a large number of exceedingly fine needles and hexagonal plates, the latter being easily mistaken for the former owing to their more or less oblique position. A good light is required to see the needles. Both needles and plates show negative double refraction. After a few days a third kind of crystal was developed, also consisting of hexagonal plates showing double negative refraction, but with a diameter of up to about 0.5 mm. These plates may enclose whole groups of cement particles. If the slides were not protected from air, a fourth kind of "biscuit-shaped" crystals, consisting of calcium carbonate, was also formed. These crystals eventually changed into rhomboids of calc spar. Finally, after some time, the fine needles and plates, as well as unchanged particles of cement, became covered with a transparent, colloidal

envelope, which at first appeared in the form of minute drops, and later coalesced until it completely surrounded the crystals and particles.—A. G. L.

Cement mortar; Efflorescence on —. H. Urbach. Tonind.-Zeit., 1909, 33, 306.

WITH many Portland cements, after hardening, an unsightly efflorescence of calcium carbonate appears on the surface. The author has tried the addition of trass for the purpose of removing the objectionable white calcium salts. A cement was taken which gave a great deal of efflorescence, and pats were made with 1 part by volume of the cement to 2.5 parts by volume of building sand. Pats were also made with 1 volume of cement, 0.5 volume of trass, and 2 volumes of building sand. After setting, the pats were laid in a room, the atmosphere of which was nearly saturated with moisture, and once a day the whole surfaces of the pats were moistened with water from a small syringe, but little pools of water were not allowed to form in any depressions, these conducting very much to the deposition of salts. On the fifth day a slight trace of salt appeared on the pats without any addition of trass, and increased from day to day, although the pats were washed with water every second day. This was discontinued on the twentieth day, and then a uniform milde-w-like skin formed. The pats to which trass had been added showed a slight layer on the twelfth day, which, after careful washing, did not recur, and after 90 days no change was observed, except a general change in colour. Pats to which 0.2 and 1.0 part by volume of trass had been added gave similar results, but some pats to which trass of a different origin was added did not give quite such satisfactory results. It may be that in these latter experiments the alkalis played an important part as conditioning agents, but were modified in their action by the silicic acid, or that the trass used was not suitable for the purpose on account of its composition.—W. C. H.

PATENTS.

Kilns for burning bricks, pipes, pottery, and the like; Regenerative gas fired —. D. Hadlington and E. Webster, West Bromwich. Eng. Pat. 3255, Feb. 13, 1908.

A SERIES of small gas producers and regenerators are arranged alternately side by side along each side wall of the kiln. Primary air flues admit air to the gas producers, and secondary air flues admit secondary air to the regenerators. The secondary air flues have dampers so arranged that the secondary air passes through one half of the regenerators alternately, into a common hot air passage serving for all the regenerators. Uptakes lead the hot secondary air from the common hot air passage to the outlets from the gas producers into the kiln. Instead of a series of small producers, the gas may be generated in a single external producer, and led from it by means of flues into a series of gas chambers.—O. R.

Lime kilns. J. Ward and The Barnstone Blue Lias Co., Ltd., Barnstone. Eng. Pat. 3740, Feb. 19, 1908.

A CONTINUOUS, vertical, shaft kiln, consists of two main divisions, the upper part containing the raw material, and the lower part the burning and burnt limestone. The two portions are separated by two obstructing arches, disposed at right angles to one another, and intersecting at the top, so as to form a skeleton dome. The fuel is delivered into the kiln immediately below the obstructing arches by way of a series of inclined shoots, which pass through the walls of the kiln and of the arches themselves, thus allowing the fuel to be fed symmetrically and at various points of the burning zone, both in the centre and also nearer to the walls of the kiln. Air is drawn through two wickets at the base of the kiln, and is pre-heated in its upward passage by the descending burnt material. The main body of the kiln is composed of an outer wall of concrete and an inner brick lining, the space between the two being utilised to form subsidiary flues, which supply air to and effect the thorough combustion of the smoke.—O. R.

Kilns for burning brick and the like; Construction and building of continuous — W. Laverty, Belfast. Eng. Pat. 4579, Feb. 29, 1908.

AN oblong brick kiln of the continuous type, divided into chambers, is provided with main vapour flues in its outer walls to draw off hot vapours from the chambers, and also with a central main hot air flue. The vapour flues and the hot air flue are connected at one or both ends of the kiln, and the joint flue opens into the chimney stack at a level above the entry of the smoke flue. The different flues are provided with the usual transverse connections for each chamber, and with dampers.

—A. G. L.

Cement; Process for making — E. J. Winslow, Chicago, Ill. U.S. Pat. 913,794, Mar. 2, 1909.

A "RELATIVELY water-proof cement" is obtained by grinding together a dry powdered cement and about 2 per cent. of an anhydrous water-proofing compound containing an inorganic alkaline substance, e.g., a mixture of lime and an oleaginous substance.—A. G. L.

Wood; Process for the impregnation and preservation of — J. Chateau and J. Merklen, Paris. Eng. Pat. 4929, March 4, 1908.

SEE Fr. Pat. 386,441 of 1908; this J., 1908, 686.—T. F. B.

X.—METALS AND METALLURGY.

Magnetite; Determination of ferrous iron in — R. B. Gage. J. Amer. Chem. Soc., 1909, 31, 381—385.

HALF a gram of ore is weighed into a 50 c.c. platinum crucible which is fitted, as closely as possible, into an opening in an asbestos board. The ore is thoroughly moistened with water and a couple of coils of platinum wire added to prevent bumping. A cold mixture of 10 c.c. of hydrofluoric acid and 15 c.c. of dilute sulphuric acid (1:3) is added and the crucible quickly covered with a tightly fitting lid. A 6 in. funnel, coated inside with paraffin wax and connected to a carbon dioxide generator is placed over the crucible and its junction with the asbestos board made air-tight by pouring a little water round it. In a few minutes, the air is completely expelled by the carbon dioxide and decomposition started by heating the contents to boiling and maintaining at gentle ebullition. When decomposed, i.e., after a little more than 5 min., the crucible is allowed to cool and when the steam inside has condensed, the crucible, with the lid held tightly on, is placed in a beaker containing 400—500 c.c. of cool boiled distilled water. The contents of the crucible are quickly mixed with the water, a solution containing sufficient calcium phosphate to precipitate the excess of hydrofluoric acid added and the solution titrated, as rapidly as possible, with a standard solution of potassium permanganate, the first permanent coloration being taken as the end point. Control determinations should also be made. Duplicate assays should agree within 0.1 c.c. of permanganate. The strength of the permanganate solution is such that 1 c.c. is equivalent to 0.0025 grm. of iron. The calcium phosphate solution for 0.5 grm. of ore is made by suspending 5 grms. of calcium carbonate in 50 c.c. of distilled water and slowly stirring in 10 c.c. of 85 per cent. orthophosphoric acid. The excess of sulphuric acid remaining after decomposing the ore is sufficient for titrating but should not be enough to prevent the precipitation of the calcium fluoride.—F. R.

Chrome-iron ore; Smelting of — in a blast-furnace with air enriched in oxygen. P. Monnartz. Metallurgie, 1909, 6, 160—167.

SMALL working scale experiments were made to smelt a chrome-iron ore in a model blast-furnace. The ore used contained 55.60 per cent. of chromic oxide and 15.21 of iron oxide. It was mixed with sand, marble, coke, and tar, and formed into briquettes, which were carbonised. The fluxes were calculated so as to give a ratio of silica to bases in the slag of about 0.7. The furnace used was first heated to a red heat, and the briquettes and coke then fed in. A blast was used containing 35 per

cent. of oxygen at a plus pressure of 115 mm. In the most favorable experiment, 12 kilos. of briquettes were smelted in 35 minutes, giving 3 kilos. of a metal containing 60.5 per cent. of chromium, 31.5 of iron, 6.2 of carbon, 1.0 of silicon, and 0.82 of manganese; together with about 12 kilos. of slag containing 9.4 per cent. of chromic oxide. The slag was sufficiently liquid to separate readily from the metal.—A. G. L.

[Gold] Cyaniding of sand; Use of the vacuum pump in the — W. A. Caldecott. J. Chem. Met. and Min. Soc., S. Africa, 1909, 9, 240—241.

THE vacuum pump was used in the early days of the cyanide process, but did not prove satisfactory, owing to its having been mainly employed with slimy charges in which the high resistance to percolation caused the solution to flow in paths of least resistance. At the Simmer Deep-Jupiter plant, vacuum pumps have been installed and found to be entirely satisfactory with the modern charges of sands free from slimes. The solutions are first allowed to drain by gravitation, the vacuum pumps being used to accelerate the flow of the last, slowly draining portion of the liquid, and to reduce the amount of solution retained by the sands. Suction is further continued in order to draw air into the charge, and thereby increase the solvent action of the cyanide. In addition to effecting a considerable saving of time, the more complete draining of the charge, at each stage, reduces the amount of wash solutions necessary, and enables a more thorough removal of the dissolved gold to be effected.—F. R.

[Gold] Precipitation from cyanide solutions by zinc shavings and dust; A comparison of results and costs. A. J. Clark. J. Chem. and Min. Soc., S. Africa, 1909, 9, 222—224.

COMPARISONS between the results obtained by the various methods employed for the precipitation of gold and silver from cyanide solutions, frequently lose much of their value owing to the fact that such comparative tests, on a working scale, are seldom made in the same plant. At the Homestake Mine, the practice has been to precipitate the solutions of greater strength and value by means of zinc dust, and the weaker solutions by shavings in the ordinary zinc boxes. These weaker solutions are now being precipitated with zinc dust, and the author gives data comparing the two methods over periods of 12 and 9 months respectively. It was found that the precious metals in solutions containing less than 0.03 per cent. of potassium cyanide, were not completely precipitated by zinc shavings and it was therefore necessary to increase the strength of such solutions before passing them through the zinc boxes, but when using zinc dust for precipitation, solutions containing as little as 0.015 per cent. of cyanide can be successfully treated. The following are the monthly averages and costs:—

	Zinc shavings.	Zinc dust.
Cost of precipitant	\$129.56	\$51.15
Precipitant used per ton of solution, lb.	0.1724	0.1284
Per cent. of precious metals precipitated	91.7	94.4
Value of precipitate, per lb.	\$2.35	\$4.03
Cost per dollar recovered	0.1608	0.0449

—F. R.

Gold bullion; Determination of silver in — E. H. Taylor. Eng. and Min. J., 1909, 87, 543.

THE method used at the Great Boulder Perseverance Mine, W. Australia, is to fuse, in a porcelain crucible, 0.5 grm. of bullion with 1.5 grms. of metallic cadmium, using sufficient potassium cyanide to completely cover the metals during the fusion. The fusion should be complete in about 5 minutes, and after cooling, the cyanide is dissolved out with water and the button of alloy placed in a flask with 20 c.c. of water. The water is boiled and four successive additions of 10 c.c. of nitric acid are made, and the boiling continued for an hour. The solution is

diluted to 150 c.c., 10 c.c. of iron alum indicator added, and the silver titrated with a standard solution of ammonium thiocyanate, containing 1.6 grms. of the pure salt to the litre. The thiocyanate solution is standardised against pure silver, each c.c. being equivalent to about 4.483 parts of silver per 1000. A "check" is run at the same time, a preliminary fire assay being made to ascertain the approximate composition of the bullion.—F. R.

Gold; Determination of — in copper bullion. F. F. Hunt. Eng. and Min. J., 1909, 87, 465.

When dissolving copper bullion in concentrated sulphuric acid, enough cuprous sulphide is formed to interfere with cupellation, unless preceded by more than one scorification. Most of the sulphide is formed at the beginning of the action, but if acid containing copper sulphate is used to dissolve the bullion, very little sulphide is formed. *Assay*.—Heat a mixture of 80 c.c. of concentrated sulphuric acid and 25 c.c. of a 16 per cent. solution of copper sulphate, and when hot enough to commence immediate action, add 1 assay ton of the borings. When action ceases, cool and add while stirring, 400 c.c. of water, just boil and filter. Dry the residue, ignite the paper and scorify together with 35 grms. of lead and 1 grm. of silica, then cupel and part. If silver is also to be determined, the filtrate is oxidised with potassium permanganate and 1 c.c. of a saturated solution of sodium chloride and 10 c.c. of a 10 per cent. solution of lead acetate added and well stirred. After standing over night, the precipitate is collected, and added to the gold residue, the two being scorified together.—F. R.

Lead button in cupellation; Temperature of the —. R. H. Bradford. J. Ind. and Eng. Chem., 1909, 1, 181—184.

The temperature of the lead button and of the interior of the cupel during cupellation was determined by means of a Le Chatelier pyrometer, the couple at the hot junction being protected by a thin coating of fireclay. It was found that before "driving" commenced, the temperature of the molten lead rose to 900° C. or above—approximately the melting point of litharge. Temperature determinations at different stages showed that when once the lead commenced to oxidise rapidly, the temperature of the button rose owing to the heat of oxidation of the lead, this heat being sufficient to keep the litharge melted even when the cupel was drawn forward to a cooler position in the muffle. Cupellation proceeds so long as the heat developed is sufficient to keep the litharge melted, and this can be attained by maintaining the temperature at 650°—750° C. about $\frac{1}{4}$ in. above and near the front of the cupel and working with a gentle draught through the muffle. The formation of "feathers" of litharge is due to the temperature of the air surrounding the cupel falling well below the melting point of litharge.—A. S.

Copper blast-furnaces gases; Power from —. R. Schorr. Eng. and Min. J., 1909, 87, 459—460.

At the Krüg-Hütte in the Mansfeld district, Germany, the waste gases from the copper smelting furnaces, instead of only being used for raising steam and heating the blast as at the other works in the district, are utilised for running gas engines which have a total rated capacity of 4650 h.p. The engines are directly connected to three-phase generators of 50 cycles and 3000 volts, the power being distributed by underground cables. The ore smelted consists of a bituminous copper schist containing from 1.8 to 3.7 per cent. of copper, and a lime-stone containing small quantities of copper, the average value of the charge being 2.8 per cent. of copper and 0.0155 per cent. of silver. About 630 tons of ore are smelted daily, with an approximate consumption of 20 per cent. of coke, the furnaces producing between seven and eight hundred thousand cubic feet of gas per hour. The furnaces are cut off from the mains during charging but the supply of gas is kept fairly constant by only cutting off one furnace at a time. The gases, after being washed to remove dust, sulphur, arsenic, etc., contain 9 to 11 per cent. of carbon dioxide and 19 to 24 per cent. of carbon monoxide, the remainder being nitrogen. They

have a calorific value of about 68 B.T.U. per cu. ft., or about two-thirds that of an average iron blast-furnace gas. On account of the fluctuation in the proportion of carbon monoxide and dioxide a special gas generating plant has been installed to enrich the gas when necessary. The total expenditure in 1907 for operating and fixed charges, amounted to about £6000, equivalent to a third of a penny per kilowatt-hour.—F. R.

Iron in brasses and bronzes; Determination of —. I. M. Bregowsky and L. W. Spring. J. Ind. and Eng. Chem., 1909, 1, 187—188.

It is pointed out that in general the iron content of brasses and bronzes is given as a trace, or rarely as more than 0.2 per cent. The authors cite a number of analyses in which the content of iron in different brasses and bronzes ranged from 0.34 to 1.47 per cent. Unless the iron content is exceptionally high, about one-half of it will be found in the ignited stannic oxide, and may be recovered by fusing the latter with sodium carbonate and sulphur, treating with water, precipitating any dissolved ferrous sulphide by addition of ammonium chloride, and determining the iron in the ferrous sulphide by titration or gravimetrically. The remainder of the iron may be precipitated with ammonia either before or after the separation of the copper.—A. S.

Iron; Action of steam on —. J. A. N. Friend. Chem. Soc. Proc., 1909, 26, 90.

The author has studied the action of steam on iron at temperatures ranging from 100° to a red heat. It is found that pure steam free from carbon dioxide, has no action on pure iron until those temperatures are reached at which the steam begins to dissociate, when a black oxide (presumably Fe_3O_4) is produced. The conclusion is drawn that the usual statement that steam is decomposed by red-hot iron is not true. The reaction really takes place in two stages, involving (i.) the dissociation of the steam, and (ii.) combination of the iron with the dissociated oxygen.

Manganese ore discovery in Cape Colony. Bd. of Tr. J., Mar. 25, 1909. [T.R.]

The "Cape Times" of 27th February reports a discovery of manganese ore in the Devil's Peak (Table Mountain). The deposits, which are believed to be rich, cover an extent of about 1000 acres, stretching from the first peak of the Devil's Peak on the Cape Town side, right through to the side above Groot Schuur. The quality of the manganese is stated to be very good, but until the deposit is developed it is difficult to compute what quantity of ore it may contain, though it is apparent that the reef is many feet in thickness. The prospectors have already dug out about 120 tons of first-class ore.

Carbon monoxide; Action of — on chromium, nickel, manganese, and their oxides and alloys. G. Charpy. Compt. rend., 1909, 148, 560—561.

CARBON monoxide at 1000° C. is practically without action on nickel. It reduces nickel oxide at that temperature completely to metal. Manganese and rich ferromanganeses absorb the gas at 1000° C. and later evolve part of it again; no carbon dioxide is formed, but a mixture of manganous oxide and carbon is left in the boat. Trimanganic tetroxide is reduced by carbon monoxide at 1000° C. to monoxide, which is absolutely stable in the circumstances of the experiment. Chromium similarly furnishes a mixture of chromium sesquioxide and carbon; carbon monoxide is without action on the sesquioxide. In chrome-steels similarly treated, the carburisation of the iron (this J., 1903, 911) and the oxidation of the chromium go on together as though the metals were separate and independent.—J. T. D.

Common metals; Gases occluded in —. B. Delachanal. Compt. rend., 1909, 148, 561—563.

The author describes experiments made many years ago by Dumas and himself, but hitherto unpublished. The metals were heated to redness in a porcelain retort in *vacuo*, and the evolved gases collected. Blank experiments

showed that there was no diffusion of the furnace gases through the substance of the retort.

The following results were obtained :—

Metal.	Weight.	Gas obtained.				
		Hydrogen.	Methane.	Carbon monoxide.	Carbon dioxide.	Nitrogen.
	grms.	c.c.	c.c.	c.c.	c.c.	c.c.
Aluminium	200	88	—	—	—	—
Magnesium	20	12.0	—	4.1	—	—
"	40	35.06	—	2.44	—	—
Zinc	100	18.15	—	1.65	0.50	—
Tin	1000	3.25	2.80	2.05	1.94	1.56
Platinum	144	0.47	2.67	4.05	0.70	1.31
Iridioplatinum ..	146	3.65	0.87	3.60	0.60	1.08
	150	2.64	0.31	3.19	0.51	0.55

The gases from spongy platinum consisted almost entirely of carbon dioxide and uncombustible gas.—J. T. D.

Aluminium; Influence of impurities on the thermo-electric properties and electrical resistance of —. H. Pécheux. Compt. rend., 1909, **148**, 627—628. (See also this J., 1907, 1147).

THE impurities found in commercial aluminium are iron, silicon, and carbon. The author has found that the thermo-electric E.M.F. of aluminium-copper couples prepared with samples of aluminium containing various small quantities of these impurities, are nearly the same, but that they are increased by the presence of iron. Silicon appears to have an effect similar to that of iron. Both impurities increase the electrical resistance of aluminium. Recently fused aluminium was used by the author in his experiments. He points out that the purity of this metal may be ascertained with certainty from its thermo-electric properties and resistance.—L. E.

Metals; Application of the microscope to the study of —. W. Rosenhain. J. Roy. Soc. Arts, 1909, **57**, 349—356.

PATENTS.

Drying [air] blast for metallurgical furnaces. F. W. Harbord, London. Eng. Pat. 4424, Feb. 27, 1908. (Compare Eng. Pats. 25,112 of 1906, and 10,525 of 1907; this J., 1907, 1282; 1908, 287).

THE air-blast is dried by leading it through a chamber containing bricks or lumps of dried peat impregnated with calcium chloride and ferric chloride. The peat is prepared by saturating it with a strong solution of calcium chloride, preferably mixed with 5 to 10 per cent. of a solution of ferric chloride of equal strength, and then drying the saturated peat. Three chambers containing the prepared peat are used in connection with each blowing plant. The air-blast is dried in one of the chambers, and is then led through a second chamber in order to cool the drying material which has just been dehydrated, while the contents of the third chamber are being dehydrated by passing air at about 210° C. through, and circulating hot gases round the outside of the casing. Each chamber in turn serves to dry the blast.—A. T. L.

Steel; Process and apparatus for the manufacture of —. Dellwik-Fleischer Wassergas Ges.m.b.H. Fr. Pat. 395,131, Oct. 10, 1908.

IRON ore is charged into the upper of two chambers, from which it falls, from time to time, through a trap, into the

lower chamber. This lower chamber is surrounded by an annular space, communicating with both chambers, and provided with passages through which air is blown in. Water-gas is forced into the lower chamber near the top, reduces the iron ore to spongy metallic iron, and emerges at the bottom of the chamber into the annular space, where the excess of combustible gases is burnt, the products passing upwards through the ore in the upper chamber, thus preheating it. It is essential that the ore in the lower chamber should be at a temperature of about 700° C. before the water-gas is introduced, as otherwise, below this temperature, decomposition of carbon monoxide into carbon and carbon dioxide would take place, and the resulting iron would be too rich in carbon for steel-making. At the end of the reduction, the temperature of the lower chamber is raised to 900°—1000° C. for a short time. The resulting spongy iron, which is no longer pyrophoric, is charged into baths of molten steel or iron, which engulf it at once and prevent oxidation of the finely-divided metal.—A. G. L.

Silver, plate, and the like; Electro-chemical process for cleaning —. A. M. Kohler, London. Eng. Pat. 15,962, July 27, 1908.

THE article to be cleaned is immersed in an aqueous solution of one or more alkalis (e.g., sodium hydroxide), in contact with an aluminium alloy, e.g., an alloy consisting of 80 per cent. of aluminium, 10 of barium, 8 of calcium, 1 of sodium, and 1 of silicon and other impurities. The alloy dissolves in the alkaline solution with evolution of hydrogen at the surface of the silver or plated article, which then only requires rubbing to render the surface bright.—A. G. L.

Iron from tin-plate scrap; Process of preparing merchantable —. E. A. Sperry, Brooklyn, N.Y. U.S. Pat. 906,321, Dec. 8, 1908.

THE tin-plate scrap is placed in a perforated vessel, which is immersed in a boiling solution of caustic alkali to remove fat, etc. The scrap is next washed by immersing the vessel in a tank of water, and is then freed from solder by passing it through a highly-heated furnace chamber. The scrap next passes between mangling rolls, preferably moving in opposite directions at different speeds, and provided with teeth. The shredded scrap is then compressed, a little at a time, into a number of billets, which, from their construction, possess a laminated structure. These billets are evenly placed along the walls of a number of (e.g., five) perforated vessels, which are then placed, one above the other, on a frame-work carried by a central shaft revolving on a ball-bearing in a chamber provided with valved entry pipes for hot air and chlorine, and valved exit pipes leading to two condensers. The billets are heated in this chamber whilst under centrifugal strain, by passing hot air through the chamber and revolving the shaft; this treatment opens up the billets along their lines of lamination; the billets may also be heated and cooled alternately. Chlorine is next admitted to the chamber, the stannic chloride vapours being condensed alternately in the two condensers. The last traces of stannic chloride are removed by heating the billets strongly in hot air, after which they are washed in a solution of caustic alkali to prevent rusting of the iron. If necessary, the porous black iron-scrap so obtained is consolidated by hammering or pressing before smelting.—A. G. L.

De-tinning; Process of —. H. M. Fernberger, Dollar Bay, Mich., and W. W. Murray, Philadelphia, Pa. U.S. Pat. 913,275, Feb. 23, 1909.

TINNED metal is treated with a solution of chlorine in anhydrous carbon tetrachloride. The carbon tetrachloride removes grease, etc., and dissolves the stannic chloride which is formed. The solution is separated from the residue, and the stannic chloride is precipitated by adding water.—A. T. L.

Metallurgical process. G. Moore, New York. U.S. Pat. 913,535, Feb. 23, 1909.

IN order to separate metals from their ores, the ores are heated with a salt which reacts to form a volatile com-

pound of the metal, and this volatile compound is separated by forcing steam through the heated mass and finally condensing the steam.—A. T. L.

Metals; Process of separating — in solution. H. H. Dow, Midland, Mich., and W. S. Gates, Worthington, Canada, Assignors to The Ontario Nickel Co., Ltd., Worthington, Canada. U.S. Pats. 913,708 and 913,709, March 2, 1909.

To a solution containing a number of dissolved metals, a reagent is added capable of producing more or less insoluble compounds with these metals, the compound of one of the metals being slightly less soluble than those of the others. The reagent is added in quantity equivalent to the amount of this metal present, and the resulting precipitate is agitated with the liquid until the more soluble compounds first precipitated have been redissolved, when the precipitate is separated from the liquid, and the operation repeated so as to separate the remaining metals. Or else, the quantity of reagent first added is less than that corresponding to the least soluble metal; the precipitate and liquid are agitated as above, and the precipitate is separated; after which a further quantity of the reagent, equivalent to, or somewhat in excess of, that needed to precipitate the remainder of this metal, is added, the second precipitate removed, and the operation repeated as before.—A. G. L.

Precious metals from ores; Process of extracting —. J. Kitzee, Philadelphia, Pa. U.S. Pat. 913,735, Mar. 2, 1909.

Precious metals are extracted from their ores by means of cyanide in the presence of the anolyte resulting from the electrolysis of a nitrogen compound, this anolyte containing an oxide of nitrogen.—A. G. L.

Gold and silver from slimes; Extraction of —. A. F. Crosse, Fr. Pat. 395,230, Oct. 14, 1908. Under Int. Conv., Mar. 2, 1908.

The slimes are treated with an extracting (cyanide) solution, thorough extraction being ensured by blowing air into the mass, which is contained in a conical separator. This separator is provided in its upper part with an internal conical partition, leaving an annular space inside the walls of the separator, from which clear liquid only overflows into a pipe leading to a vessel in which the solution is freed from the gold and silver it contains by means of zinc. The solution then flows into an intermediate vessel, from which it is returned by means of a pump to the separator, extraction with the same liquid being continued until the slimes are exhausted. The liquid may be brought up to proper strength by the addition of cyanide at any time.—A. G. L.

Antimony ores; Process and apparatus for the treatment of —. E. Chatillon. First Addition, dated Oct. 2, 1908, to Fr. Pat. 382,504, Oct. 3, 1907 (this J., 1908, 287).

The capacity of the furnace previously described is increased by inserting in each chamber 4 or 5 pipes or, preferably, vertical gas retorts of fireclay or cast-iron. The lower ends of these pipes or retorts are partly open and partly closed, and are supported on the inner walls of the chambers; the upper ends pass through the roof of the furnace into the open, and are provided with removable covers. The pipes or retorts are charged with a mixture of antimony oxide and carbon; the reduced antimony melts and falls into the main bath of the chamber. Removal of cinders from the chambers is facilitated by continuously moving the grills, which may form endless bands. Condensation of antimonial vapours in the escaping gases is now effected by forcing the gases to pass upwards through a number of vertical compartments placed in a tower, water being allowed to drop down through the compartments, each of which is further provided with a number of horizontal partitions, the spaces between these partitions being half filled with bundles of wood, etc.—A. G. L.

Minerals of all kinds; Treatment of — to obtain the metal they contain. B. Junquera, Fr. Pat. 394,719, Sept. 26, 1908. Under Int. Conv., Feb. 8, 1908.

The mineral is mixed with carbon and fluxes, powdered, and, if necessary, formed into nodules, and introduced into the upper end of a rotatory kiln, 20–30 m. long, and inclined at 3°–5°. Coal dust and air are injected into the lower end of the kiln, which is surrounded by a fixed crucible-shaped chamber. In its passage down the kiln, the mineral is first reduced to metal, which is fused in the lower part of the kiln, and collects in the fixed chamber. For those metals (e.g., iron) which are so difficultly fusible that the quantity of hot reducing gases produced is far in excess of that required for the reduction of the ore, the kiln is divided into three parts, an upper rotating kiln in which reduction takes place, a lower rotating kiln in which the reduced metal is fused, and an intermediate fixed chamber connecting the two rotating kilns, and provided with a flue regulated by a damper through which the excess gases are allowed to escape.—A. G. L.

(B.)—ELECTRO-METALLURGY.

Electrolytic iron; Preparation, composition, and thermal properties of —. A. Müller. Metallurgie, 1909, 6, 145—160.

SEVERAL hundred grams of nearly pure electrolytic iron were obtained in a comparatively short time by proceeding in two distinct stages. In the first stage, a good steel or wrought iron is used as anode in an electrolyte consisting of a 30 per cent. solution of ammonium ferrous sulphate, working either according to Burgess and Hambuechen's process (this J., 1904, 667) but at ordinary temperatures, with N.D.₁₀₀=0.8 ampère at 1.5 volts, or according to Maximowitsch (this J., 1905, 140) with N.D.₁₀₀=0.5 ampère at 0.8—1.2 volts. The anodes were contained in porous earthenware cells, and were cleaned every day by brushing with hydrochloric acid; the anolyte was renewed daily; the catholyte was protected from dust by a layer of paraffin, and was not stirred. The cathodes consisted of carefully cleaned tin-plate or lead foil. The electrolytic iron so obtained which contained 0.08—0.10 per cent. of total fixed impurities (of which carbon amounted to about 0.07 per cent.) was then further purified by two further electrolyses, using concentrated ferrous chloride solution as electrolyte, with N.D.₁₀₀=0.7 ampère at 1—4 volts. The precautions taken were similar to those mentioned above, except that the anolyte was used over again, after daily precipitation with barium chloride and removal of sulphate and dirt by filtration in the morning. The electrolytic iron so obtained contained silicon, 0.0040—0.0042 per cent.; phosphorus, 0.0032—0.0041; sulphur, trace; manganese, trace to 0.0045; carbon, 0.0230—0.0440; total, 0.0311—0.0542 per cent. of fixed impurities, in addition to 0.018—0.112 per cent. of hydrogen and 0.014—0.018 per cent. of nitrogen. The current efficiency varied from 66—98 per cent. Microscopic examination under moderate powers showed a lamellated structure; larger magnification showed a star-like structure. The iron was melted in a magnesia crucible placed in a specially constructed electrically heated vacuum furnace. After melting once it still contained 0.011 per cent. of nitrogen, and it required fusing seven times to free it from hydrogen, as shown by the disappearance of the spontaneous evolutions of heat during the heating, which are caused by hydrogen. The most marked of these heat evolutions occurred at 1210° C. The melting-point was found to lie between 1485° and 1525° C. Arrest points were observed at 894° and 766°—759° C. during cooling, and 917° and 765°—774° C. respectively during heating.

—A. G. L.

[Iron and chromium] Passivity in acid solution. Part II. J. Alvares. Z. Elektrochem., 1909, 15, 142—144.

IN continuation of Sackur's work (this J., 1908, 986), the author has investigated the passivity of iron and chromium by the same method. In general the passivity of these two metals resembles that of nickel. In the case of iron, however, the critical strength of current rises, with increased dilution, to a maximum and then falls. Addition of chlorine ions to the acid has no effect on the critical strength of current. The author's experiments confirm the well known observation that a rise in temperature hinders the assumption of the passive state. Chromium resembles nickel in that the critical current strength sinks with increasing dilution of the electrolyte. It is rendered passive more easily than iron, for it becomes passive in moderately concentrated hydrochloric acid in which iron and nickel remain active.—J. C. C.

PATENTS.

Electroplating; Apparatus for —. G. A. Lutz, Plainfield, N.J., U.S.A. Eng. Pat. 21,243, Oct. 8, 1908.

THE hollow article to be plated is supported as the cathode in a tank, and suitable anodes are arranged inside and outside of the article. One terminal of a generator is connected to both the inner and outer anodes, and a make and break mechanism, controlled by hand or by clockwork, is arranged in the inner anode circuit. The

latter may thus be broken without interfering with the outer anode circuit, so that the deposition of metal on the outside of the article is carried on for a greater length of time, thus avoiding the thicker inner coating which is obtained when the current passes for the same period through both anode circuits.—B. N.

Furnaces: Electric —, with electrodes, serving for the manufacture of homogeneous iron and steel. T. Levoz. Fr. Pat. 395,084, Oct. 8, 1908.

The furnace is divided into two receptacles, A and B, the former having an acid lining, and the latter a basic one of magnesia or dolomite. It is supported upon two trunnions, one of which is hollow for the supply of air to the compartment, A. The electrodes are withdrawn from the chamber, B, and the vessel is turned through an angle of 90°, so that the blast pipe is at the side of the chamber, A. Molten cast iron is introduced into A through the opening, O, and a charge of scrap iron or mild steel is placed in the chamber, B. The cast iron is blown, as in a Bessemer converter, for the production of pure iron, and the flames passing into B serve to melt the material in this chamber. The furnace is then rotated into its original position, so as to pour the metal from A into B, and the metal is refined by a further electric heating. The electrodes are lowered into B, and the arc is enlarged by means of a solenoid placed as a shunt across the arc, the intensity of the magnetic field being increased or diminished by means of a regulator. A regulator is also arranged in the electrode circuit, in order to prevent an abrupt load being placed on the machine when starting the current, and to automatically cut out the current when the arc is broken.—B. N.

Metal: Electrolytic deposition of — on hollow articles. E. Friedheim, Paris. Eng. Pat. 4744, March 2, 1908. Under Int. Conv., March 4, 1907. Addition to Eng. Pat. 7563 of 1907; dated March 30, 1906.

XII.—FATTY OILS, FATS, WAXES, AND SOAPS.

Cotton seed "foots": Composition of —. H. Wagner and J. Clement. Z. Untersuch. Nahr. Genussm., 1909, 17, 266—268.

Two samples of "foots" obtained in the refining with alkali of two cotton-seed oils from Egyptian seed had the following respective composition:—Water, 42.67 and 34.35; mineral matter, 10.52 and 8.34; unsaponified oil, 10.55 and 23.70; saponified oil, 31.56 and 33.18; and unsaponifiable matter, 2.30 and 1.91 per cent. The unsaponifiable matter (crude phytosterol) in the original impure oil was 0.884 per cent., whilst the purified oil contained 0.595 per cent. Hence during the purification a considerable proportion of the crude phytosterol is thrown down with the "foots." The phytosterol from these samples of "foots," purified by the method of Windaus and Hauth (this J., 1907, 69, 1150), melted at 137.5°–138° C., and formed an acetate melting at 126° C. The acetate was saponified with sodium hydroxide solution and the phytosterol recrystallised from alcohol, but no substance of higher m.p. than 138.6° C. could be obtained. Hence in the light of these experiments the phytosterol of cottonseed oil must be regarded as consisting of an individual substance. This conclusion was also arrived at by Heiduschka and Gloth (this J., 1908, 1161), who examined the phytosterol by the method of Windaus and Hauth. On the other hand fractional crystallisation from alcohol of the crude phytosterol, previously purified by means of petroleum spirit, gave a different result. The substance was thus separated into a phytosterol melting at 139° C., and a smaller quantity of a phytosterol melting at 132°–133° C., and yielding an acetate (m.p. 120° C.) and a bromide (m.p. 114°–115° C.). The authors therefore conclude that the phytosterol of cottonseed oil consists of at least two distinct phytosterols. The crude phytosterol was contaminated with a brown oily substance containing 0.556 (and 0.584) per cent. of sulphur.—C. A. M.

Glycerol: New, highly sensitive reactions for detection and identification of —. G. Denigès. Compt. rend., 1909, 148, 570—572.

For the detection of appreciable quantities of glycerol, the following reactions, based upon its conversion into dihydroxyacetone, are described. Glycerol (0.08–0.10 grm., or 1 c.c. of a 10 per cent. solution) is heated with 10 c.c. of freshly prepared bromine water (0.3 c.c. of bromine dissolved in 100 c.c. of distilled water) for 20 minutes in boiling water, boiled to expel all the bromine, and allowed to cool. The solution is then submitted to the following tests:—*Colour reactions.*—The reagents are codeine, resorcinol, thymol, and β -naphthol, the method being the same as that previously described (this J., 1909, 219) save that instead of the solution of dihydroxyacetone there mentioned, 0.4 c.c. of the test solution (with the codeine reaction, 0.2 c.c. + 0.2 c.c. of water) is used; in the resorcinol and thymol reactions the mixture is not heated. The colours obtained are similar to those previously described. *Colour reactions in presence of potassium bromide.*—The reagents are 5 per cent. alcoholic solutions of salicylic acid and guaiacol; the method is the same as that previously described (this J., 1909, 219), save that, as above, 0.4 c.c. of the test solution is used. Salicylic acid gives an intense violet red colour; with guaiacol, the colour is deep blue. *Hydrazine reactions.*—(1) The test solution (0.5 c.c.) is mixed with 0.5 c.c. of a reagent prepared by dissolving 1 c.c. of liquid phenylhydrazine in a mixture of 4 c.c. of acetic acid and 20 c.c. of a 10 per cent. solution of crystallised sodium acetate. The whole is heated for 20 minutes in boiling water and left to cool for an hour. An abundant yellow precipitate of glycerosazone consisting of twisted stellate needles and rounded yellow granules is thus obtained. (2) Five c.c. of the test solution are distilled with 1 c.c. of sulphuric acid, 1.5–2 c.c. of distillate being collected. One c.c. of this distillate is treated with 1 c.c. of the above-described hydrazine reagent, a crystalline precipitate of methylglyoxalosazone being slowly formed.

Reduction reactions.—The test solution (0.5 c.c.) is treated with 0.5 c.c. of Nessler's reagent; after 2 minutes, mercury is precipitated. With Fehling's solution and Fehling's solution treated with ferrocyanide, cuprous oxide and cuprous ferrocyanide respectively are obtained under the same conditions. To detect very small quantities of glycerol, the material must be extracted; a quantity of less than 0.10 grm. of the residue from this extract being treated as above described.—L. E.

Cholesterol and allied bodies; Occurrence and distribution of — in the animal kingdom. C. Dorée. *Bio-Chemical J.*, 1909, 4, 72—106.

ENTIRE animals typical of the great subdivisions of the animal kingdom were examined by the author, the finely divided material being mixed with plaster of Paris and sand, dried, coarsely powdered, and extracted with ether, and the cholesterol, etc., in the ethereal extracts separated by the usual methods. From the results the author concludes that cholesterol is invariably present in vertebrata, whilst in invertebrata it is widely but not uniformly distributed, its place being sometimes taken, e.g., in insects and echinodermata, by closely-allied substances. It is probable that each species of sponge is characterised by containing a different member of the cholesterol group. All the animal cholesterols examined, with the possible exception of *spongosterol* from the sponge *Suberites domuncula*, were isomeric with and possessed properties similar to those of ordinary cholesterol.—C. A. M.

Oil from cotton-seed or other oleaginous material; Process for extracting —. J. E. Mills, Chapel Hill, N.C. Assignor to H. B. Battle, Montgomery, Ala. U.S. Pat. 913,751, Mar. 2, 1909.

THE cotton-seed, or other material, is introduced into a vertical column, at about half the height of the latter, while hot carbon tetrachloride is introduced at the top of the column. The oil seed rises through the carbon tetrachloride which extracts the oil, and the exhausted material, after passing through a layer of water above the carbon tetrachloride, is removed by suitable means at the top of the column. The carbon tetrachloride containing the dissolved oil is drawn off at the bottom of the column, and the solvent and oil are separated and recovered by a process of distillation.—W. P. S.

Soap; Process for the manufacture of albumose —. P. Runge, Hamburg, Germany. Eng. Pat. 22,441, Oct. 22, 1908. Under Int. Conv., Sept. 24, 1908.

A CLARIFIED alkaline solution of albumose obtained from casein in the usual way is treated with the exact amount of a fatty acid or mixture of fatty acids required to neutralise the alkali, and the resulting solution of albumose soap is concentrated *in vacuo* or otherwise. Or the albumose may be dissolved in a solution of an alkali, or an alkaline-earth, or it may be a "sulpho-alkaline solution of albumose." The proportions preferred are such as to yield a product containing from 33½ to 50 per cent. of albumose.—C. A. M.

Esparto grass; Recovery of by-products from —. C. F. Cross and D. Russell. Fr. Pat. 395,250, Oct. 14, 1908. Under Int. Conv., Apr. 14, 1908.

THE cuticle of the esparto grass contains a wax of industrial importance; a portion of this cuticular wax is removed mechanically in the process of dusting the grass prior to its conversion into paper pulp, whilst another portion passes into the alkaline boiling-liquor, from which it may be separated during the process of concentration by skimming or straining. The wax may be prepared in a pure condition from either of these sources by digestion with nitric acid or other equivalent oxidising agent, or by extraction with volatile solvents in a continuous extraction apparatus.—J. F. B.

(A.)—PIGMENTS, PAINTS.

Indigoid dyestuffs; Application of — as oil colours. A. Eibner. *Chem.-Zeit.*, 1909, 33, 229—230, 243—244, 254.

THE author's experiments were made with synthetic Indigo, the symmetrical Thioindigo B and BA and Vat Red, and the unsymmetrical Thioindigo Scarlet R. When used as water colours the Thioindigo colours remained unaffected after exposure for 1 year and 7 months. When mixed with linseed oil and with a white pigment, the symmetrical Thioindigo colours, on the other hand, were completely bleached in some cases in less than 2 days; the rapidity of the bleaching was independent of the white pigment used (white lead, zinc white, lithopone free from zinc oxide, and barium sulphate). Bleaching occurred also in the dark, though less rapidly than in the light. The symmetrical Thioindigo BA mixed with zinc white was also bleached with more or less rapidity when used with various drying and non-drying fatty oils, oil of turpentine, and copaiba oil, whereas under similar conditions synthetic Indigo and the unsymmetrical Thioindigo Scarlet R gave satisfactory results. From the experiments with the fatty oils it would appear that there is some relation between the ease with which the oils become rancid and the rapidity of bleaching of the colour. It is probable that the bleaching is due, at least in part, to aldehydic compounds, formed when the oils become rancid. Experiment showed that formaldehyde solution was capable of bleaching Thioindigo BA. This cannot be the sole cause however, for mixtures of Thioindigo BA, zinc white, and pure vaseline were also completely bleached in 8 days. With dammar and mastic varnishes as vehicles, the symmetrical Thioindigo colours remained unaffected after exposure for 6 months, and the author considers that, especially for dark shades, these dyestuffs could be used in practice with a turpentine oil varnish as vehicle. They can also be used in the form of lakes, the pink aluminium lake of Thioindigo BA when used with linseed oil remaining unaffected after exposure for 30 days.

Condensation product [of phenol and formaldehyde], and method of making the same. L. H. Baekeland, Yonkers Township, N.Y., U.S.A. Eng. Pat. 21,566, Oct. 12, 1908. Under Int. Conv., Oct. 15, 1907.

PHENOL, or phenolic substances can be made to react with a molecular proportion of formaldehyde in the presence of a basic condensing agent such as ammonia, aniline, sodium hydroxide, etc. The proportion of base used is never more than one-fifth of that required to convert the phenol completely into a phenolate. If the condensation is carried out at moderate temperatures, the product is oily, and soluble in alcohol or acetone. Heat and pressure convert it into a solid body, insoluble in alcohol, acetone, or in acid or alkaline reagents. (See Fr. Pats. 386,627 and 386,628 of 1908; this J., 1908, 686, 690.)—F. SHDN.

Condensation products from o-cresol and formaldehyde; Process for preparing resinous. — F. L. Blumer. Ger. Pat. 296,904, Dec. 7, 1907.

A CLEAR, odourless, resinous product, easily soluble in alcohols, ketones, and ether, but sparingly soluble in turpentine oil, hydrocarbons, and fatty oils, is obtained by the condensation of pure o-cresol with formaldehyde in presence of alkalis. 80 kilos. of potassium hydroxide solution (50° B.) are added to a mixture of 100 kilos. of o-cresol and 100 kilos. of formaldehyde: the mixture is kept boiling for two hours, preferably with exclusion of air, and the product is precipitated by dilute sulphuric acid; it melts to a clear mass in boiling water.—T. F. B.

Mixing printing inks. Eng. Pat. 8623. See I.

(C.)—INDIA-RUBBER, &c.

Rubber production in Ceylon. Bd. of Tr. J., March 25, 1909. [T.R.]

RUBBER generally in the low country, where planted in suitable soil, is a success. Some of the drier districts suffered somewhat last year from the abnormally dry weather, but, generally speaking, the growth was good. A much smaller acreage was opened during 1908 than for four years past, owing to the fall in prices. A new method of tapping, which promises to be a success, should greatly economise labour and cost of working.

Raw rubber; Cause of "tackiness" in —. D. Spence. Z. Chem. Ind. Kolloide, 1909, 4, 70—76.

AMONGST the causes which have been suggested in explanation of the production of "tackiness" in raw rubber, is the action of micro-organisms. This view merits further investigation, but it should be borne in mind that bacterial action occurs not on the rubber itself, but in the rubber on the various impurities present. The effect of bacterial activity upon the rubber itself, if any, can only be indirect. Enzymes may possibly also have an indirect effect. The author's experiments deal with the action of sulphuric acid in bringing about "tackiness," and lead to the conclusion that the change undergone by the rubber is one merely affecting the physical (or possibly the chemical) state of aggregation. Such a change is known to occur in the cases of certain sorts of Maranhao and Matto-Grosso rubber, which have been coagulated with sulphuric acid. *Funtumia elastica* latex, which is not coagulated by small quantities of sulphuric acid, was selected for the purposes of the investigation. 100 c.c. of the latex were dialysed for a whole day in running water, then "pasteurised" by heating for 10 minutes at 80° C., and filtered into a sterile flask. 50 c.c. of this completely sterile, homogeneous latex were transferred to each of two Erlenmeyer flasks, and to the one were added 10 c.c. of N/10 sulphuric acid, whilst to the control flask, 10 c.c. of sterile water were added. Both flasks were kept in an incubator at 35° C. for about one month, and their condition noted from time to time. At the end of this period the latex to which sulphuric acid had been added was found to be completely coagulated, whereas in the other sample the globules had

merely coalesced to a cream, which was readily broken up on shaking. The rubber was precipitated in each case by the addition of 100 c.c. of absolute alcohol, and subsequent heating. The rubber from the two tests differed very greatly; that from the acidified latex was very soft and plastic, and was destitute of tensile strength and "nerve." The other was a very good sample of rubber. Further examination showed that:—(1), the weight of the two samples of rubber was the same, within narrow limits; hence no appreciable oxidation could have occurred in the case of the acidified sample; (2), the resin content of the two samples was the same within the limits of experimental error (8.43 and 8.50 per cent.); (3), the viscosity of solutions of the two rubbers differed greatly, that of the solution of the rubber from the acidified latex being much the lower of the two; (4), the elementary composition of the rubber "hydrocarbon" was the same in each case, both samples containing about 3 per cent. of oxygen; (5), the bromides obtained from the two samples of rubber by Budde's method were identical in properties and composition, containing 66.13 and 66.17 per cent. of bromine respectively, instead of the theoretical 70.17 per cent. The change in properties of the rubber must therefore be due merely to some change in the physical state of aggregation of the colloidal particles, or in the degree of molecular complexity of the caoutchouc molecule. The author briefly discusses the bearing of these results on the question of the durability of vulcanised rubber, referring to the markedly destructive action of traces of free sulphuric acid, and suggesting care in the use in mixings of rubber coagulated by means of "Purub" (hydrofluoric acid) (see this J., 1908, 1029, 1074).—E. W. L.

PATENTS.

Rubber, bonite or vulcanite; Method of manufacturing goods of — [from waste rubber]. O. C. Immisch, Finchley. Eng. Pat. 3659, Feb. 18, 1908.

WASTE rubber, ground into the form of crumb, is mixed with a volatile oil which is not deleterious to rubber, for example, cajeput oil, in the proportion of about 0.1 per cent. of the mass. The mixture is subjected, while under slight pressure in a mould, to a temperature of 220°—280° F., in order to volatilise the oil and expel all air from the interstices of the rubber waste. The mass is then compressed and afterwards cooled. The operations of heating, compressing, and cooling may be repeated in order to attain greater density.—E. W. L.

Rubber, bonite, or vulcanite; Method of manufacturing goods from —. O. C. Immisch, Finchley. Eng. Pat. 3940, Feb. 18, 1908.

WASTE rubber in the form of crumb (hard or soft), and advantageously mixed with a volatile, non-deleterious oil (e.g., cajeput oil), having a boiling point slightly lower than the temperature employed in the subsequent process, is placed in a mould of slightly greater volume than that of the article to be produced. The mould is closed under pressure, heated to from 220° to 280° F., and while still hot submitted to such pressure that the volume of the contents is reduced to approximately that of the article to be produced. The pressure is maintained while the mould is cooling, and when cool, the latter is clamped and reheated to the same temperature, after which it is put under pressure again to cool. By the repetition of this series of operations, an article of greater density than that of the original rubber can be produced.—E. W. L.

Resilient material for use as a filling for elastic tyres and for other purposes and a method of and means for making and applying the same. R. A. Morris, Rossendale. Eng. Pat. 3816, Feb. 20, 1908.

RUBBER or a mixture of rubber with boiled oil, resin, or similar substances is well mixed with a mineral oil solvent, preferably spindle oil, and then a solution of a vulcanising agent (sulphur chloride) in spindle oil is added. After thorough mixing, the mass is run into a mould or other object designed to receive it, and subjected to pressure. The mass sets in about 30 minutes.—A. S.

Rubber; Process of reclaiming devulcanised —. E. E. A. G. Meyer, New Brunswick, N.J. U.S. Pat. 913,218, Feb. 23, 1909.

RUBBER waste, which has been devulcanised by treating it with a mixture of two solvents, of which one is a rubber solvent, while the other is not, is "depolymerised" by heating it at temperatures exceeding 120° C. with a neutral resinous soap, and subjecting the mass to a high mechanical pressure during this treatment. The neutral soap may be prepared from the resin of natural rubber.—E. W. L.

XVI.—SUGAR, STARCH, GUM, &c.

Juice [Sugar]; Boiling of thick — in cane sugar factories. H. C. Prinsen-Geerligs and H. E. Weitkamp. Reports of the Experimental Station for the Java Sugar Industry, No. 8; Z. angew. Chem., 1909, 22, 203.

THE authors deal with the various boiling processes used in Java. Masecuite from cane juice granulates much more readily than that obtained from beet juice. In Java, the molasses can be desaccharified to such a

degree that the apparent purity only amounts to 27—28 per cent. (actual purity 38—40 per cent.). With beet molasses, the lowest purities are 51 to 52 per cent. (actual purity 54—55 per cent.). Contrary to former usage, boiling the juice until it becomes stringy is now only applied to the working up of mother syrups of low purity. —L. E.

Sucrose in bagasse; Determination of —. H. C. Prinsen-Geerligs. Reports of the Experimental Station for the Java Sugar Industry, No. 7; Z. angew. Chem., 1909, 22, 202—203.

THE method recommended by the author in Java for determining sucrose in bagasse, consists in extracting the material with boiling water for 10—12 minutes. On the basis of results obtained in Egypt, Pellet and Nais have stated that this method gave values which were much too low, and they recommend the Zamaron process (see also this J., 1909, 253). The author has shown that if bagasse, freed from sugar by alcoholic extraction, is treated with boiling water, a dextro-rotatory, gummy or hemicellulose-like substance is dissolved, as a result of which, the values obtained by the Zamaron method are too high. The strikingly low sugar-content of the bagasse from several of the recently cultivated varieties of cane, is due to the small proportion of parenchyma in these canes; in the bagasse, the parenchyma contains more water than do the vascular bundles or rind; consequently with a low proportion of parenchyma, the bagasse is drier and therefore poorer in sugar.—L. E.

Sucrose and hydrated maltose; Optical determination of mixtures of —. J. Pieraerts. Bull. Assoc. Chim. Sucr. et Dist., 1909, 26, 650—652. (See also this J., 1906, 716; 1909, 253.)

THE mixture (2.5 grms.) is dissolved in 40—50 c.c. of tepid water, the cooled solution being made up to 100 c.c. (solution A). (1). Twenty-five c.c. of solution A are treated with 2 c.c. of alumina cream and 2 drops of strong ammonia, made up to 50 c.c., filtered, and polarised in a 200-mm. tube at 20° C. (2). Fifty c.c. of solution A are treated with 10 c.c. of a freshly prepared 20 per cent. solution of citric acid in a round-bottomed flask of 1-litre capacity. Some fragments of porous material are added, the flask is fitted with a reflux condenser, and the solution heated to boiling as rapidly as possible on a wire gauze. Boiling is continued for exactly 8 minutes, the solution is then cooled rapidly and transferred to a 100 c.c. flask, treated with 2 c.c. of alumina, made up to volume, filtered, and polarised in a 200-mm. tube at 20° C. If α and α' are the readings in angular degrees before and after hydrolysis, the amounts of sucrose (x) and hydrated maltose (y) in 1.25 grms. of the mixture may be found from the equations,

$$2 \frac{66.5}{100} x + 2 \frac{130}{100} y = \alpha$$

$$\text{and } -2 \frac{19.80}{95} x + 2 \frac{130}{100} y = \alpha'$$

whence $x = 0.57246(\alpha - \alpha')$
and $y = 0.384615\alpha - 0.2928363(\alpha - \alpha')$

THE author has analysed mixtures of known proportions of sucrose and hydrated maltose by the above-described method. The results show that the use of citric acid under the given conditions insures the complete hydrolysis of the sucrose whilst the maltose is quite unaffected.

—L. E.

Cane sugar [sucrose] and maltose; Inversion of — by ferments. A. E. Taylor. J. Biol. Chem., 1909, 5, 405—407.

THE author finds that the inversion of sucrose follows the course of a monomolecular reaction and is proportional to the concentration, thus confirming the work of O'Sullivan and Tompson (this J., 1890, 816, 1049) and of Hudson (this J., 1908, 1076). The author's work also shows that the same holds true for the inversion of maltose.—J. A.

Starch and its constituents; Progress of oxidation and hydrolysis of — by the action of hydrogen peroxide. Z. Gatin-Gruzewska. *Compt. rend.*, 1909, 148, 578—580.

ONE per cent. solutions of amylopectin, amylose (this J., 1908, 415), and starch, on heating to 131° C. for 20 minutes, present similar opalescent appearances, and give ultramarine- or indigo-blue colorations with iodine. These solutions (100 c.c.), on treatment with hydrogen peroxide (5 c.c.), behave as follows:—*Amylopectin*.—In 24 hours, the solution is quite clear; it is coloured intensely red by iodine, and is precipitable by large quantities of alcohol. The intensity of the iodine reaction gradually decreases, and disappears in about 7—8 days, and at this stage, the solution yields scarcely any precipitate with alcohol. The acidity increases till about the fifteenth day and then remains constant at a value equivalent to 1.2 c.c. of $N/10$ alkali. The reducing power attains a maximum on the third day and then decreases. *Amylose*.—In 24 hours the liquid is opalescent and gives a violet-blue colour with iodine (the colour becomes intensely blue if alkali is added to the liquid and the whole is neutralised; this shows that reversion-amylose is present). On the fourth day, a clear liquid and a flocculent precipitate separate; the former is coloured a faint red (by iodine) and is precipitated by much alcohol; the latter gives the reaction of reversion-amylose. The acidity curve is similar to that of amylopectin, save that the constant value is somewhat less; the maximum reducing power is attained somewhat later than in the case of amylopectin. *Starch*.—The behaviour is similar to that of a mixture of amylopectin and amylose. The reversion to amylose, even in very concentrated solutions of starch, is never so great as in solutions of pure amylose. The amylopectin and the erythro-dextrin appear to act as a solvent towards the amylose. This should explain the importance of complete liquefaction of the starch paste in diastatic actions. Amylopectin and amylose present distinct differences in behaviour under the action of enzymes and of hydrogen peroxide. The decomposition of the "micelles" of amylopectin appears to be simultaneous, whilst that of the "micelles" of amylose appears to be successive. Both amylose and amylopectin pass through the (erythro-) dextrin stage. It may be that in nature, other peroxides can produce these reactions; if so, the reactions would be of great biological importance. —L. E.

XVII.—BREWING, WINES, SPIRITS, &c.

Fermentation with yeast; Influence of ethyl alcohol on —. M. Kochmann. *Biochem. Zeits.*, 1909, 16, 391—398.

THE author has made comparative experiments on the influence of ethyl alcohol on the fermentation of dextrose with yeast, and has found, that at concentrations of 1:300—1:500, the alcohol accelerates the fermentation. In this, as in many other cases, the product of metabolism exerts a stimulating influence on the activity of the organism. It is highly probable that this stimulating action of the alcohol consists in an increased production of zymase; the investigations of various workers have shown that alcohol does not appear to exert a favourable influence on the enzyme itself. At somewhat higher

degrees of concentration, the final influence of the alcohol consists in a retardation of the decomposition of the sugar, though initially, the stimulating influence on the cell-activity is still perceptible.—L. E.

Unmalted cereals; Application of diastases present in — to the preparation of alcohol and "amé." Y. Tanaka. *J. Coll. Eng., Imp. Univ., Tokyo*, 1908, 4, 205—217.

RYE is the only grain which contains sufficient diastase to enable it to be used industrially, without the assistance of malt, for the manufacture of spirit (this J., 1908, 134). Other grains, such as wheat or barley, contain a diastase which has a powerful saccharifying action but is deficient in starch-liquefying power. The author has shown, on the other hand (this J., 1908, 462), that millet and other small-grained cereals secrete a diastase which has a high liquefying power but weak saccharifying action. Consequently a combined extract of both kinds of grain is capable of being used as a substitute for malt in the saccharification of gelatinised starch. The extract is prepared by mixing a 10 per cent. infusion of wheat-bran with a 10 per cent. infusion of ground millet in equal proportions. The most favourable temperature for saccharification is 50°—55° C.; the time depends on the quantity of diastatic enzymes present, but with a proportion of about 10 per cent. of the mixed diastatic grains on the weight of the material, saccharification is well advanced after 3—5 hours. "Amé" is a sweet yellow syrup prepared in Japan by the action of malt on steamed rice. The author has prepared this substance without malt by the action of 360 c.c. of the 10 per cent. infusion of mixed cereals on 300 grms. of "glutinous" rice, previously gelatinised, for 4 hours, and evaporation of the filtered wort. The product differed from the commercial "amé" only in the fact that it gave a red reaction with iodine owing to the presence of erythro-dextrins. Otherwise the composition and the ratio of maltose to dextrin were very similar. The author has also applied the mixed diastatic extracts to the preparation of alcohol, on the experimental scale, from rice, other Japanese grains, and potatoes, without the assistance of malt. The results, when compared with those obtained by the use of malt, showed practically identical yields of alcohol. The sweet mashes obtained without malt showed the reaction for erythro-dextrin, but this disappeared in the course of fermentation. Since the cereals which have served for the preparation of the diastatic infusions may be mixed and steamed with the next main batch of starchy material, there is no waste of starch and the economy, as compared with the malting process, is very considerable.—J. F. B.

Caramel; Detection of — in wine, cognac, and beer. A. Jägerschmid. *Z. Untersuch. Nahr. Genussm.*, 1909, 17, 269.

ONE hundred c.c. of the sample are mixed with albumin solution (equal parts of fresh white-of-egg and water) and heated with continual stirring until the albumin coagulates. The filtrate is evaporated on the water-bath to the consistence of a syrup, and divided into two portions, one of which is mixed with ether and the other with acetone. Portions of the ethereal solution are allowed to evaporate spontaneously on porcelain, and the residues tested with one or two drops of a freshly-prepared solution of resorcinol in hydrochloric acid (1 gm. to 100 c.c.). In the presence of caramel, a persistent cherry-red coloration is immediately obtained. The acetone solution is filtered, if necessary, and mixed in a test-tube with an equal volume of concentrated hydrochloric acid. A carmine red coloration indicates the presence of caramel.—C. A. M.

Wines; Volumetric determination of total sulphurous acid in —. C. Blarez and L. Chelle. *Bull. Assoc. Chim. Sac. et Dist.*, 1909, 26, 690—693.

RIPPER's method for determining the total (free and combined) sulphurous acid in wine is not very exact; the results are nearly always higher than those obtained by the method proposed by Haas. The latter method is accurate, but it is intricate and takes much time. The following process does not take more than 20—25 minutes, and gives results agreeing well with those obtained by the

method of Haas. Two c.c. of syrupy phosphoric acid and some ignited pumice are placed in a flask of about 250 c.c. capacity heated on a water-bath. The flask is fitted with a tap-funnel (of at least 50 c.c. capacity), and a jacketed delivery tube; the other end of this tube passes through a rubber stopper fitted into one neck of a double-necked receiver containing 20 c.c. of 4 per cent. solution of sodium hydroxide. The other neck of the receiver is fitted with a rubber stopper and stopcock, the latter communicating with an air-pump. The apparatus is evacuated to a pressure of 20–30 mm., and the pump is cut off. Fifty c.c. of the wine are slowly introduced from the tap-funnel into the distilling flask, the funnel being subsequently rinsed with a little water; care must be taken that air does not enter the apparatus. Throughout these operations, the flask is heated on the water-bath. Distillation is continued until the residue is pasty. The tap-funnel is then opened to admit air, the receiver is detached, the distillate is acidified with 10 c.c. of dilute (1:3) sulphuric acid, and titrated with $N/20$ or $N/50$ iodine with starch paste as indicator.

PATENTS.

Yeast; Desiccation of — G. F. Humphrey, London. Eng. Pat. 3166, Feb. 12, 1908.

YEAST, having the consistence of cream is brought in contact with an inert, sterilised and vesicular absorbent material, and the mixture is then dried by a current of dry, cold, sterilised air. A suitable absorbent is prepared by fermenting a dough composed of ordinary wheat flour to which is added about 25 per cent. of gelatinised rice. The dough is made up into large loaves which are then thoroughly baked and sterilised. This absorbent bread may be used either in the form of crumbs or slices, which are thoroughly dried and mixed or sprinkled with the yeast-cream. The quantity of bread required amounts to about 70 per cent. of the weight of pressed yeast which itself contains 70–75 per cent. of moisture.—J. F. B.

Saccharification; Converters for — G. Dupont. Fr. Pat. 394,838, Oct. 2, 1908.

THE conversion vessel is provided with a cover forming a convex basin which is perforated with holes around its periphery. At the centre of the cover is a vertical chimney, which possesses a grilled opening in its wall at a certain height. The froth produced by the ebullition of the liquid rises up the chimney until it reaches the opening; it is there condensed by contact with the cold air as it emerges, and it then falls back on the outside of the cover whence it returns to the pan by way of the peripheral holes. The gases and vapours collected by a hood ascend further up the chimney, and the liquid which condenses in the upper part is collected in a channel which conveys it away from the apparatus.—J. F. B.

Fermented beverages; Composition of matter for use in preparing — M. Wallerstein, New York. U.S. Pat. 908,630, Jan. 5, 1909.

THE composition is more particularly intended for the preparation of brewing waters, and consists of 75 parts of precipitated calcium sulphate, 20 parts of potassium chloride, and 5 parts of magnesium sulphate. If the nature of the water to be treated is such that other salts are also required, the same are added to the mixture, and the composition of the latter altered accordingly.—W. P. S.

Beer and other liquids; Filtering — H. Wanderscheek, Rixdorf, Germany. Eng. Pat. 3837, Feb. 20, 1908.

THE material of which the filter is composed, for instance, cotton, linen, jute, wood, straw, etc., is treated with benzene, ether, or other solvent, and afterwards with a very dilute solution of an alkali. The material is then

boiled with a suitable acid and, if desired, is again treated with the solvent. The treatment completely removes fatty substances which impart a disagreeable taste to the beer or other liquid. (Reference is directed to Eng. Pats. 397 of 1886 and 801 of 1892; this J., 1887, 39; 1893, 133.)—W. P. S.

Alcoholic liquids; Process for distillation and rectification of — V. Slavicek. Fr. Pat. 394,949, Oct. 5, 1908.

THE crude vapours are split up into two parts, and the phlegms, after being deprived of the head products, are sprayed into the other portion of the crude vapours, which has been subjected directly to rectification, being deprived of its head products but containing the "tail" products. The two portions thus mixed at the boiling point become saturated with "tail" products without being saturated with alcohol. The vapours so obtained are purer than usual, the concentration in the rectifying column is lower and consequently the column of tail products is not so high. All the impurities existing after rectification are treated together at as high a concentration and temperature as possible and are returned for the purpose of heating the head products purifier. The columns receive automatically sufficient phlegms and alcoholic vapours to maintain the zone of tail products at a constant height, and all the parts of the columns which communicate with each other are maintained under the same pressure. The crude vapours passing from the distillation column to the rectifying column are caused to ascend a wide pipe so that no spray from the wash can be carried through.—J. F. B.

Brewing processes. H. Breker, Cologne, Germany. Eng. Pat. 1884, Jan. 28, 1908. Under Int. Conv., Jan. 29, 1907.

XVIII.—FOODS; SANITATION; WATER PURIFICATION, AND DISINFECTANTS.

(A.)—FOODS.

Flours; Chemically treated — E. F. Ladd, H. P. Bassett, and H. L. White. Chem. News, 1909, 99, 110–112, 126–129, 133–136. (Compare this J., 1909, 157.)

NITRITES and nitrates are among the products formed in flour as the result of bleaching with nitrogen peroxide. In the flour for one loaf (373 grms.) as much as 1.313 mgrms. of sodium nitrite were found. Bread made from this flour contains from one-third to one-half this quantity. The oil from unbleached "patent" flour, properly extracted and purified, contains no nitrogen, that from bleached flour gives a strong nitrogen reaction. The oil of unbleached flour has an iodine value of 101; the same flour when bleached yielded an oil with an iodine value of 84. Obviously the bleaching agent acts on the fat of the flour. It has been claimed that artificial bleaching brings about results similar to those of natural ageing, but the authors find that the oil from flour aged for nine months shows no reduction in iodine value, whereas oil from the same flour bleached and aged showed a reduction of 17 units. The proportion of nitrates in the bread increases as the nitrites decrease, the amount of nitrite destroyed depending on the method of baking and being least in products in which baking powder or "soda" is used. Gluten from the unbleached flour was digested by pepsin and hydrochloric acid in about 5 hours; that from the bleached flour required nearly twice as long under the same conditions. Baked glutes from the same flours showed similar variations, but were digested much more quickly; the same is true for the bread made from such flours. The gluten, baked gluten, or bread from unbleached flour was digested more quickly by pancreatic ferments than that from the same flour bleached. Bread made with bleached flour possessed greater keeping qualities. Apparently the bleaching agent does not act to form a low-nitrated nitro-starch product, but it acts on some part of the gluten, forming compounds which give a diazo reaction liberating nitrogen when treated with acid. Experiments with rabbits show that toxic bodies are

produced in flour as the result of bleaching. The alcoholic extract of unbleached flour was without effect on rabbits, that of bleached flour caused their death within a few hours; that of over-bleached flour caused their immediate collapse and death. Aqueous extracts behaved similarly. The death is not due to acidity, as the neutralised aqueous or alcoholic extracts of over-bleached flour caused death within a few hours.—E. F. A.

Gluten; Physical state of — T. B. Wood and W. B. Hardy. *Proc. Roy. Soc.*, 1909, B., 81, 38—43.

THE authors' experiments deal with the influence of electrolytes upon the physical state of gluten. It is shown that very dilute acid destroys the cohesion of gluten and causes it to be dispersed into an opaque colloidal solution or hydrosol. If, however, the strength of the acid is increased, a critical point is reached at which the gluten remains as coherent as in distilled water. The concentration at which the gluten retained its coherence was as follows in the case of different acids:—Sulphuric acid, 0.017 *N*; nitric acid, 0.02 *N*; hydrochloric acid, 0.05 *N*; oxalic acid, 0.15 *N*; and phosphoric acid, 2.00 *N*. Gluten is dispersed when repeatedly washed with distilled water owing to the influence of the carbonic acid present. The addition of a small proportion of salt to a hydrosol precipitates the gluten, and salts therefore reduce the disintegrating effect of acids and alkalis upon the cohesion of gluten, and in sufficient concentration completely neutralise their action. The action of alkali upon the cohesion is similar to that of acid, except that the protein in the resulting hydrosol is negatively charged, whereas in that formed by acids the electric charge is positive. Alkali added to a hydrosol not only neutralises any acid present, but also reacts with the protein, and is neutralised, with the formation of new ions. The general conclusion arrived at is that the physical state of gluten depends upon the potential difference between the fluid and the particles of protein. The development of this potential difference may be explained by the hypothesis that it is due to differences in the speed of the ions of electrolytes present, the colloid particles being, as it were, charged with an excess of the most rapidly moving and penetrating ions. Or it may be accounted for by the chemical hypothesis that proteins are amphoteric electrolytes, reacting with acids and alkalis to form salts, the nature of which depends upon conditions of temperature, concentration, and inertia due to internal surfaces within the solution becoming electrified. Experimental facts against the first view are brought forward.—C. A. M.

Yeast; Carbon dioxide value of pure compressed — alone and mixed with starch. T. J. Bryan. U.S. Dept. Agric., Bureau Chem., Bull. No. 116, 25—28. *Chem. Abs.* (Amer. Chem. Soc.), 1909, 3, 555—556.

THREE test yeasts were prepared, a pure yeast, a mixture of 10 lb. of maize starch, 70 lb. of yeast and 16 lb. of water, and a mixture of 10 lb. of potato starch, 70 lb. of yeast and 19 lb. of water. These preparations were allowed to act for 24 hours on 100 c.c. of 10 per cent. sugar solutions to which 75 c.c. of water had been added in a suitable flask provided with calcium chloride tubes. The loss in weight owing to the carbon dioxide expelled was ascertained hourly. This was repeated daily until the yeasts were 14 days old. Tables are given showing the comparative loss in each test; the results are uniformly low in the case of the yeasts mixed with starch. When run for 24 hours the potato and maize starch preparations gave an average yield, on samples 1—14 days old, of 83.4 per cent. and 86.2 per cent. respectively of the loss where pure yeasts were used. When run for 12 hours only, the loss was 79.5 per cent. and 83.1 per cent. respectively. Baking tests were also made, dough containing 650 grms. of flour, 500 grms. of water and 10 grms. of yeast mixtures being used. Pure yeast yielded a greater volume of bread in each case; the average on 5 trials made when the yeasts were 2, 5, 12, 13, and 14 days old was for pure yeasts 2439 c.c., and for maize starch yeast 2240. The conclusion is drawn that starch does not improve the keeping quality of yeast and is to be considered merely an adulteration.

Milk treated with bichromate; Action of light on — A. Gascard. *Compt. rend.*, 1909, 148, 580—582.

SEVERAL workers have pointed out the objections to potassium bichromate as a means of preserving milk intended for analysis (see this J., 1909, 36). The author has found, however, that milk, which has been treated with bichromate, may be kept for a considerable period before analysis without suffering serious alteration, provided that it is protected from light. Thus, 2 samples of the same milk, containing 1 gm. of potassium bichromate per litre, were kept for 2 months, one exposed to light, the other in darkness. At the end of this period, the samples presented very different aspects. In the former, a greenish-white coagulum was suspended in a rose-grey liquid, the fat had separated in small compact masses, and the acidity was high; the sample was no longer suitable for analysis. The latter was golden yellow in colour, and had not coagulated; its acidity had increased slightly; the fat readily underwent emulsification in the cold, and the sample could still be used for analysis.—L. E.

Butter fat; Determination of — in the presence of cocoanut oil. M. Monhaupt. *Chem.-Zeit.*, 1909, 33, 305—306.

FOR the determination of small amounts of butter fat in the presence of large quantities of cocoanut oil, the author recommends the following modification of Kirschner's method of separating the volatile insoluble fatty acids by means of silver sulphate (*Z. Untersuch. Nahr. Genussm.*, 9, 65):—The neutralised Reichert-Meissl distillate is treated with 0.5 gm. of silver sulphate, and filtered after standing for some time at 15°—18° C. 100 c.c. of the filtrate are mixed with 20 c.c. of dilute sulphuric acid and 30 c.c. of water, and, after the addition of a little pumice stone, distilled in Polenske's apparatus, until 110 c.c. have been collected. This is filtered and 100 c.c. titrated with *N*/10 alkali solution. The number of c.c. required multiplied by 1.21 gives the *Kirschner value*. Experimental results with mixtures containing from 10 to 35 per cent. of cocoanut oil and 1 to 2 per cent. of butter fat show that the amount of the latter may be calculated from the ratio of the Polenske value to the *Kirschner value*. A valuable means of detecting and determining such small quantities of butter fat is based upon a combination of the methods of Dons (this J., 1908, 176) and of Kirschner:—5 grms. of the fat are saponified with glycerin-sodium hydroxide solution, and the soap treated with 90 c.c. of recently-boiled water and 50 c.c. of dilute sulphuric acid and heated on the water-bath at 80° to 90° C. under a reflux condenser until a clear layer of fatty acids is obtained. The contents of the flask are then vigorously shaken, cooled, and filtered, the filtrate distilled in Polenske's apparatus, and 110 c.c. of the distillate collected and filtered. 100 c.c. of the filtrate are titrated with *N*/10 alkali, the number of c.c. consumed multiplied by the factor 1.1 giving the "new Reichert value." The neutralised distillate is then used for the determination of the "new *Kirschner value*" as described above. Both values increase steadily with an increase in the amount of cocoanut oil in a mixture of fats containing cocoanut oil and butter fat, but the increase in the new Reichert-Meissl value (due to the extracted caprylic acid) is greater than that in the new *Kirschner value*, which is to be attributed to the caproic acid. The following empirical table illustrates the relationship between the values:—

Cocoanut oil.	Butter fat.	New Reichert-Meissl value.	New Kirschner value.
Per cent.	Per cent.		
15	0	0.50	0.24
15	1	0.72	0.39
15	2	0.99	0.62
25	0	0.88	0.30
25	1	0.99	0.55
25	2	1.21	0.69
35	0	1.10	0.36
35	1	1.32	0.63
35	2	1.50	0.81

By using 20 grms. of the fat instead of 5 grms., the differences between the new Kirschner values of fats containing butter and free from butter are correspondingly increased. (See also this J., 1909, 157.)—C. A. M.

Caffeine; Determination of — in coffee. K. Lendrich and E. Nottbohm. Z. Untersuch. Nahr. Genussm., 1909, 17, 241—265.

The authors' experiments have shown that the caffeine may be quantitatively extracted by 3 hours' extraction with carbon tetrachloride from 20 grms. of coffee whether the latter be previously moistened with 2.5, 5, 7.5, or 10 c.c. of water. An addition of 50 per cent. of water is advisable, however, since the amount of soluble substances (other than caffeine) extracted is less than when a smaller proportion of water is used. Raw coffee requires to be left in contact with the water for 2 hours before the extraction, and in this respect the authors' experience differs from that of Gorter (this J., 1908, 242), who found 30 minutes' treatment sufficient. The following method is recommended as applicable to every kind of coffee:—20 grms. of the sample, ground to granules about 1 mm. in diameter and sifted, are mixed with 10 c.c. of water and allowed to stand for 2 hours (1 hour for roasted coffee) with occasional stirring. The mass is then extracted for 3 hours with carbon tetrachloride, the extract mixed with about 1 gm. of paraffin wax and evaporated, and the residue extracted first with 50 c.c. and then with three portions of 25 c.c. each of hot water. The aqueous extract is cooled and filtered, and the filtrate decolorized by the addition of 10 c.c. (30 c.c. for roasted coffee) of a 1 per cent. solution of potassium permanganate, followed, after 15 minutes, by a 3 per cent. solution of hydrogen peroxide containing 1 c.c. of glacial acetic acid per 100 c.c., which is added drop by drop. The liquid is next heated for 15 minutes on the water-bath and filtered whilst hot. The filtrate and washings are evaporated to dryness, and the residue dried for 15 minutes at 100° C., and taken up with hot chloroform. The filtered solution is evaporated, and the residue of caffeine dried for 30 minutes at 100° C., and weighed. The caffeine may also be quantitatively separated by extracting with chloroform the aqueous solution after the treatment with potassium permanganate. In cases where extreme accuracy is required, the nitrogen in the residual caffeine should be determined, and the amount of alkaloid calculated from the result. Gorter (this J., 1908, 242, 464) attributed the defective extraction of caffeine by chloroform in the absence of water to the alkaloid being present in the form of potassium-caffeine chlorogenate, which was not decomposed by anhydrous organic solvents. The authors show, however, that the tissue of the coffee bean possesses a pronounced adsorptive capacity for caffeine. Thus in experiments in which the residues previously freed from caffeine were mixed with a definite amount of pure caffeine solution, dried, and extracted for 3 hours with chloroform, benzene, or carbon tetrachloride, only traces of the alkaloid were recovered, whereas after moistening the mass with water, the caffeine could be quantitatively recovered.—C. A. M.

Export of tinned provisions to Japan. Percentage of lead in solder. Bd. of Tr. J., March 25, 1909. [T.R.]

THE Japanese Police Authorities are now enforcing Art. III. of the Regulations respecting Receptacles for Provisions and Beverages issued by the Home Office in 1900. This Article provides that solder which is in contact with the contents of the tinned goods must not consist of an alloy with more than 20 per cent. of lead, while receptacles must not be lined with an alloy of tin and lead which contains more than 5 per cent. of lead. In soldering the outer portions of tins which contain, or are to contain, provisions, no alloy must be used which consists of more than 50 per cent. of lead. Up to the present, several tins of provisions of American and French manufacture have been found to be in contravention of the last clause and have therefore been confiscated.

PATENTS.

Margarine; Manufacture of — [addition of bananas]. H. A. Snelling. London. Eng. Pat. 8279, April 14, 1908.

To every 1 cwt. of margarine are added 15 lb. of banana fruit, 2 drms. of banana essence, or 9 drms. of banana oil; where two or more of these banana constituents are employed, the quantity of each is proportionately reduced. The addition is made at the point where the fat is churned with milk; the temperature of the mixture is raised until the whole is fluid, and it is then cooled while being constantly stirred. The bananas are prepared by peeling the fruit, soaking it in water for 12 hours, and then drying and grinding it to a powder. The bananas may be baked or boiled before use.—W. P. S.

Wheat flour; Recovery of starch and protein from —. E. A. V. Klopfer, Dresden, Saxony. Eng. Pat. 19,726. Sept. 19, 1908. Under Int. Conv., Oct. 4, 1907.

In Eng. Pat. 11,159 of 1907 (this J., 1907, 1289) a saline solution was claimed for the purpose of loosening or opening up the cellular tissue of the flour. In the present invention, the structure of the protein cells is loosened by the action of an aqueous extract of green malt or malt flour, and the denaturing action of the salt is avoided. The proportion generally used corresponds to 1—3 parts of dry malt substance per 100 parts of flour, the action being carried out at the ordinary temperature, in presence of about 140 lb. of water. The action of the malt extract is due to the proteolytic enzymes contained therein, and other proteolytic extracts, e.g., papain, may be substituted for the malt. The starch is then separated by centrifugal action.—J. F. B.

Flour; Apparatus for preparing gaseous mixtures for bleaching — and similar operations. J. A. Wesener. Chicago, U.S.A. Eng. Pat. 27,218, Dec. 15, 1908. Under Int. Conv., May 14, 1908.

THE invention relates to apparatus for diluting nitrosyl chloride with air in order to form a bleaching agent for flour (see U.S. Pat. 863,684 of 1907; this J., 1907, 1025). A pump supplies a current of air at a pressure lower than that at which the nitrosyl chloride escapes from its reservoir; the escape of the nitrosyl chloride is regulated by a valve which is raised automatically by the working of the pump. The movement of the valve is capable of minute adjustment so that the quantity of nitrosyl chloride escaping at each movement can be regulated exactly.—W. P. S.

Milk; Process of pasteurising —. J. Willmann, Shelton, Conn. U.S. Pat. 913,600, Feb. 23, 1909.

A CONTINUOUSLY flowing body of milk is maintained at a temperature of from 140° to 152° F. for such a length of time as will suffice to kill the bacteria present without coagulating the albumin of the milk. The milk is then cooled.—W. P. S.

Butter manufacture. E. Schou, London. U.S. Pat. 913,920, March 2, 1909.

SEE Eng. Pat. 5810 of 1908; this J., 1908, 872.—T. F. B.

Wheat flour; Process for extracting starch and gluten from —. F. A. V. Klopfer. Fr. Pat. 394,802. Sept. 30, 1908. Under Int. Conv., Oct. 4, 1907.

SEE Eng. Pat. 19,726 of 1908; preceding.—T. F. B.

Desiccating yeast. Eng. Pat. 3166. See XVII.

(B.)—SANITATION; WATER PURIFICATION.

Lead water pipes; Action of impure surface-water on —. K. Aschoff. Z. öffentl. Chem., 1909, 15, 93—94.

THE author has recently examined a lead water-pipe which had lain for some 15 years in a sandy clay soil. The outside of the pipe was very corroded and yielded considerable quantities of lead, chlorine, nitric acid, and traces of ammonia when treated with hot water. The surrounding soil had a feeble alkaline reaction, was saturated with impure surface-water, and contained

appreciable quantities of lead derived from the pipe. Whilst most of the compounds formed by the action of the wet soil on the lead pipe were soluble and were consequently removed as the water percolated slowly through the soil, some lead carbonate was present on the pipe. The author considers that where it is necessary to employ lead pipes in such soils, the pipes should be coated with asphaltum.—W. P. S.

PATENTS.

Furnaces for destroying refuse. W. P. Hayes, West Bridgford, Notts. Eng. Pat. 9031, Apr. 25, 1908.

The furnace consists of a number of combustion chambers above which are placed drying chambers in which the refuse is dried before it is admitted to the actual furnace. The refuse is contained in a chamber at the top of the furnace, from which it is delivered by measuring hoppers into the drying chambers; a hot air channel is provided along the front of the drying chambers and openings in the wall between this channel and the chambers allow hot air to mingle with the refuse. The bottom of the drying chamber is shaped like a hopper, and by means of sliding doors, worked from the outside, the charge of dry material is admitted to the furnace proper, a fresh supply of refuse being admitted, in a similar manner, to the drying chambers. The hot air channel is in connection with the ashpits of the furnaces to which a forced draught of air is supplied.—W. P. S.

Water; Purification and clarification of —. W. McMurtrie, New York. U.S. Pat. 913,034, Feb. 23, 1909.

The process consists in adding to the water, equivalent quantities of calcium acid phosphate and a basic substance, so as to produce a precipitate of bicalcium phosphate.—W. P. S.

Water; Process of purifying —. H. Korten, Assignor to F. Y. Nichols, Chicago, Ill. U.S. Pat. 913,827, Mar. 2, 1909.

The process relates to the purification of feed water. The water is caused to flow through a tortuous passage between electrodes in order to precipitate the soluble impurities. The precipitate is drawn off, and the water is then passed through mercury so as to remove any of the precipitate which remains in suspension in the water.—W. P. S.

(C).—DISINFECTANTS.

Cresol soaps; Valuation of solutions of —. O. Schmatolla. (Chem.-Zeit., 1909, 33, 284.

The author points out that the use of acetic acid in determining the amount of water in cresol soaps proposed by Spaltcholz (this J., 1909, 256) had already been tried by him (Pharm. Zeit., 1903, No. 56), but that the different behaviour of different preparations of about the same percentage composition, and the fact that they are prepared from alkaline, neutral, or acid soaps render the process purely empirical. The author's method of analysis (this J., 1903, 885), however, is sufficiently rapid and gives very accurate results. The solvent power of a soap for cresol is best obtained from a determination of the amount of fatty acids. In order to obtain a clear solution miscible in all proportions with water, at least 19 parts of fatty acids to 50 parts of anhydrous cresol are required. If the soap was neutral, very concentrated aqueous solutions of the product solidify to a clear gelatinous mass. Too great an excess of fatty acids, as, e.g., in lysol, which contains 30 per cent., is a drawback for surgical use, since the instruments become coated with a thin film of soap. The old *liquor cresoli saponatus*, which contained about 21 per cent. of linseed oil fatty acids, gave the best results. The oil ought to be freshly saponified, however, with strong (about 25 to 33 per cent.) potassium hydroxide lye, to form a neutral soap. In concentrated solution this dissolves cresol very rapidly, and the requisite water is added subsequently. This method ensures the cresol being present in a free and active condition, and not in the form of potassium cresylate, which gradually becomes inactive.—C. A. M.

XIX.—PAPER, PASTEBOARD, &c.

Electrolytic bleaching of cellulose; comparison with the bleaching effect of bleaching powder solution. B. Fraass. Papier-Fabrikant, 1909, 7, 232—235, 257—260.

The experiments were carried out on a small scale in two vessels of the same capacity. Sulphite wood pulp was used as the material to be bleached; in one vessel it was bleached by bleaching liquor produced by the electrolysis of a solution of common salt and in the other vessel by the liquor produced by dissolving bleaching powder. The experiments were performed side by side in order to assist the comparison of the bleaching effects of the two liquors, and a common temperature was maintained. The results show that the electrolytic liquor, whether acid or alkaline, gives a better white than a solution of bleaching powder containing the same amount of chlorine per litre.—S. H. H.

Cellulose for technical purposes; Preliminary treatment of —. E. Berl. Z. ges. Schiess- und Sprengstoffw., 1909, 4, 81—83.

ALTHOUGH the molecular weight of cellulose cannot be determined, it is generally admitted that the viscosities of its solutions under comparative conditions vary in the same sense as its molecular complexity, and that the lowering of viscosity produced by chemical treatment corresponds to a depolymerisation of the cellulose. In technical operations the preparation of solutions of moderate concentration with moderate viscosity is frequently desirable, and the molecular weight of the original cellulose must be suitably reduced. Such depolymerisation may take the form of a separate preliminary treatment, as in the case of mercerisation prior to solution in cuprammonium, or regulated hydrolysis prior to acetylation, or it may proceed simultaneously with the reaction adopted for the conversion of the cellulose into a soluble derivative, as in the preparation of soluble pyroxylin by nitration at elevated temperatures. The former principle possesses the advantage of being capable of more exact control than the latter. In addition to the caustic alkalis and mineral acids, oxidising agents, such as bleaching powder, also attack the cellulose molecule, and depolymerisation accompanies the production of oxycellulose. A similar change also takes place when the cellulose is heated in presence of air at 100° C. The production of oxycellulose, however, has an undesirable effect on the mechanical properties of the product. In certain cases depolymerisation may be effected after the conversion of the cellulose into a soluble compound, as for instance, by heating a stabilised nitrate in presence of an inert gas at a temperature of 130° C. The regulation of the solubility or viscosity of a pyroxylin by increasing the temperature of the nitrating acid has the drawback of increasing the amount of the cotton which dissolves in and contaminates the acid. In Ger. Pat. 199,885 (this J., 1908, 937) a process was described for controlling the viscosity by a preliminary treatment of the cellulose, nitration being subsequently effected under the most favourable conditions. This treatment consists in heating the cellulose for a long time (e.g., 60 hours) at 100° C. in presence of a dry inert gas such as carbon dioxide or hydrogen. This treatment is under exact control and can be varied according to the condition of polymerisation of the original cellulose. In the artificial silk industry such a treatment is most advantageous for obtaining a strong flexible filament with economy of solvent and chemicals and increased output. It may substitute mercerisation in the cuprammonium process and hot nitration in the collodion process. In the preparation of sporting powders the preliminary treatment affords a more complete gelatinisation with less solvent; the process may also be adopted in the preparation of nitrocellulose for gelatinising nitroglycerin explosives.—J. F. B.

PATENTS.

Paper; Agent for use in sizing —. Curtius and Co., Duisburg, Germany. Eng. Pat. 25,183, Nov. 23, 1908. Under Int. Conv., July 15, 1908.

A MIXTURE of aluminium sulphate and magnesium sulphate in, say, equal proportions is used in place of pure aluminium sulphate in the sizing of paper.—C. A. M.

Wood-pulp and process for making same. C. Bache-Wüg, Berlin, N.H. U.S. Pat. 913,679, March 2, 1909.

"WOOD, in the form of blocks," is treated "with a solution of sodium chloride to soften (but not to remove) the lignin" it contains "to a substantial depth." The entire blocks are then ground up and the pulp thus obtained contains both treated and untreated fibres.—P. F. C.

Celluloid [non-inflammable], and process of making the same. W. J. Stevens, London. Eng. Pat. 4390, Feb. 26, 1908.

THE celluloid is prepared from a mixture of nitrocellulose, 150 parts, anhydrous zinc chloride, 100 parts; camphor, 70; amyl acetate (or an acetate of any alcohol that will not mix with water), 150; sodium carbonate, 15; all by weight. An alternative mixture consists of nitrocellulose, 150 parts; methylated spirit, 100 parts; zinc chloride, 100; camphor, 60; amyl acetate, 200; and sodium carbonate, 15. The machine in which the ingredients are mixed is heated and must be encased to prevent absorption of moisture from the atmosphere. Suitable pigments may be added to the mixture, and the above-mentioned proportions may be varied.—W. P. S.

Celluloid, horn, ebonite, etc.; Manufacture of a substitute for —. W. H. Story. First Addition, dated Sept. 29, 1908, to Fr. Pat. 353,995, May 5, 1905 (this J., 1905, 1081).

IN the preparation of condensation products of phenols and formaldehyde, the use of an accelerator of the reaction is claimed, for example alkalis and alkaline-earths and their salts, such as carbonates, phenolates, sulphophenolates, or their equivalents. When the reaction-product has attained the consistence of a thick fluid, it is poured into moulds in which it is maintained at a temperature below 100° C., for a sufficient time to allow the moisture to escape gradually. The gelatinous mass is then cautiously heated further until it is converted into a horny substance. Accelerators may also be added to the partially thickened mass in the second stage of the process. Lacquers may be prepared by the addition of alcohol or other solvent to the gelatinous mass before it is finally hardened.—J. F. B.

Cellulose products. Ger. Pat. 206,883. See V.

By-products from esparto grass. Fr. Pat. 395,250. See XII.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENTIAL OILS, AND EXTRACTS.

Cinchona alkaloids. IX. Oxidation of cinchona alkaloids to ketones. P. Rahe. Annalen, 1909, 364, 330—352.

THE author has obtained a ketone from several cinchona bases, thus supporting the view that the hydroxyl contained by them is of the nature of a secondary alcohol group. Cinchonidine was oxidised with chromic acid in the same way as, previously, cinchonine had been oxidised (this J., 1907, 1158). The substance produced from both alkaloids is cinchoninone, $C_{19}H_{26}ON_2$, m.pt. 126°—127° C. Quinine and quinidine by a similar oxidation process yield a ketone termed quinonine, $C_{20}H_{28}N_2O_2$, which is soluble in acids or alkalis, melts at 101° C., and has the rotation, $[\alpha]_D = +73.79^\circ$ in absolute alcohol at 23° C. Hydrocinchonine on oxidation yields hydrocinchoninone, $C_{19}H_{26}ON_2$. This substance crystallises from alcohol in bright yellow crystals, melting at 138° C.; $[\alpha]_D = +76.22^\circ$ at 19° C. The above ketones are being examined pharmacologically.—F. SUDN.

Essential oils. Ronre-Bertrand fils. Chem. Zentr., 1909, 1, 921—922.

Oil of linaloe seeds has an odour distinguishable from that of oil prepared from the wood of the tree, but it showed a slight dextro-rotation, whereas the latter is strongly laevo-rotatory. The oil from the seeds had the sp. gr. 0.8858 at 15° C.; $[\alpha]_D = +1.30^\circ$ at 20° C.; $n_D = 1.4655$ at 18° C.; acid value, 3.4; ester value, 30.9. It was

soluble in 1.5 vols. of 70 per cent., 2.25 vols. of 65 per cent., or 4 vols. of 60 per cent. alcohol. It contained methylheptenone, linalool, geraniol, nerol, and *l*-terpineol, its content of esters, calculated as linalyl acetate, being 10.8 per cent. *Grasse peppermint oil* had the characters shown in the following table:—

	Sp. gr. at 15° C.	d _D .	Menthol.	Menthyl acetate.
1907 oil, crude..	0.9210	—13.4'	Per cent.	Per cent.
1907 oil, rectified	0.9198	—17.6'	49.8	13.5
1908 oil, crude..	0.9156	—19.28'	53.5	13.7
1908 oil, rectified	0.9159	—16.50'	52.2	13.4
			54.9	13.3

Java patchouli oil.—The characters of eight different specimens of the oil of *Pogostemon patchouli* are shown in the following table. I. was obtained from fresh plants of the Singapore variety, cultivated in Java; II. and VIII. from dry plants of the same variety; III. was the first distillate and IV. the second distillate from fresh plants of the Java variety; V. was from dry plants of the Java variety; and VI. and VII. were from slightly and strongly fermented plants respectively of the same variety. Oils I. to VII. were distilled at Buitenzorg, Java, and VIII. by the author at Grasse.

	Sp. gr. at 15° C.	Optical rotation.	Saponif. value.	Saponif. value after acetylation.
I.	0.9662	—52.2'	2.7	20.7
II.	0.9677	—51.32'	0	12.5
III.	0.9112	+ 0.52'	4.1	33.4
IV.	0.9457	+15.18'	2.7	43.8
V.	0.9174	+ 3.24'	3.4	13.9
VI.	0.9217	+ 2.40'	2.7	34.1
VII.	0.9233	— 0.8'	2.1	32.1
VIII.	0.9888	—65.4'	3.5	24.3

I. dissolved to a clear solution in $\frac{1}{2}$ vol. or in 5 vols. or more of 90 per cent. alcohol, but between these limits yielded a turbid liquid. II., V., and VII. were soluble in 8 vols. of 90 per cent. alcohol, III. in 8.5 vols., and VIII. in $\frac{1}{2}$ vol. of 90 per cent. alcohol. IV. yielded a clear solution with $\frac{1}{2}$ vol. or with 3.5 vols. of alcohol, but a turbid liquid between these limits. VI. dissolved to a slightly opalescent solution in 12 vols. of 90 per cent. alcohol. *Oil from white Bulgarian roses* had the sp. gr. 0.8723 at 15° C., optical rotation, —2° 54'; saponification value, 11.14 (corresponding to 3.9 per cent. of citronellyl acetate); saponification-value after acetylation, 22.24 (corresponding to 7.44 per cent. of alcohols of the formula, $C_{10}H_{20}O$). The oil became solid at 14° C.; it was soluble in an equal volume of 90 per cent. alcohol and from the solution a solid paraffin hydrocarbon separated. The odour of the oil was somewhat inferior to that of the oil from red roses. *Ylang-ylang oil from Réunion* had the sp. gr. 0.9492 at 15° C., optical rotation, —30° 8'; esters (as linalyl acetate), 33.6 per cent.; total alcohols (as linalool), 40.3 per cent. It was soluble in 0.5—1 vol. of 90 per cent. alcohol, but the solution soon became slightly opalescent.—A. S.

Essential oils and the international congress for prevention of the adulteration of foods. E. Perrot. Chem. Zentr., 1909, 1, 933.

AT the congress held in September, 1908, under the auspices of the "Soc. univ. de la Croix Blanche de Genève," the following definitions were fixed. *Essential oils* are exclusively products of an extraction of the aromatic or odoriferous constituents of plants; they are given the names of the plants from which they are derived. *Oil of yellow sandalwood.*—The oil is obtained from yellow sandalwood (*Santalum album*, L.) by distillation with steam. It is colourless or light yellow, soluble in 5 parts of 70 per cent. alcohol at 20° C., and has the sp. gr. 0.975—0.985 at 15° C., and optical rotation, —10° to —20° in a 100 mm. tube. It must contain not less than 90 per cent. of santalol, and its saponification value must not be above 25. *Anise oil* is obtained from the fruits of *Pimpinella anisum* by distillation with steam. It

should have the sp. gr. 0.980–0.990 at 15° C., solidification point, 15°–19° C., and should not be dextro-rotatory (α =about -1° 50' in a 100 mm. tube). Star-anise oil which differs only in odour and taste must not be substituted for anise oil. "*Fruit essences*" must be products, in the pure condition or in alcoholic solution, obtained from the plants whose names they bear. If the essence is obtained from more than one plant, it must be termed a "compound essence," and bear the name of its chief constituent. Essences prepared from or containing synthetic products must be termed "artificial fruit essences."—A. S.

Iodine dioxide. M. M. Pattison Muir. Chem. Soc. Proc., 1909, 26, 88.

REFERENCE was made to the work of Millon, in 1844, and of Kämmerer, in 1861, on an oxide of iodine said to be composed of iodine and oxygen united in the ratio of 1:20, none of which work satisfactorily proved the existence of the compound.

The compound, IO_2 , or I_2O_4 , has been prepared by the dehydration and partial deoxidation of iodic acid by heating that acid with concentrated sulphuric acid. Two methods of analysing iodine dioxide were described. It was shown that the interactions of this oxide and oxalic acid, in the presence of sulphuric acid, at 100°, and with boiling water, are severally represented by the equations:

Iodine dioxide is a pale yellow, crystalline solid of specific gravity 4.2; it is decomposed at about 130° into iodine and oxygen. The molecular weight of the compound has not been determined. The reactions of the oxide with acids and with various reagents were described; in most of these interactions, iodine pentoxide and iodine are produced. Iodine dioxide is slightly soluble in cold concentrated sulphuric acid; 100 c.c. of the acid dissolve 1.54 grms. of the oxide at 15° to 20°. Inasmuch as iodine dioxide forms a compound with sulphur trioxide having the composition, $\text{I}_2\text{O}_4 \cdot 3\text{SO}_3$, the oxide has slightly basic properties. This compound is not decomposed by heating to 100°, but begins to give off iodine, oxygen, and sulphur trioxide at about 120°. Incidentally, it was shown that iodic anhydride and sulphur trioxide combine, when heated together at 100°, to form a compound which has the composition, $\text{I}_2\text{O}_5 \cdot 2\text{SO}_3$. The slightly basic characters of the two oxides of iodine emphasise the connexion between iodine and manganese.

Glycerophosphate of lime; U.S. Customs decision. Bd. of Tr. J., March 25, 1909. [T.R.]

GLYCEROPHOSPHATE of lime, which, though occasionally dispensed medicinally in its imported form, is almost always used in combination with other drugs in the preparation of elixirs, is not a medicinal preparation within the meaning of paragraph 67 of the Tariff, but is dutiable as a chemical compound under par. 3 of the Tariff at 25 per cent.

Monobromobenzene; Note on some commercial samples of —. J. H. Coste, Analyst, 1909, 34, 98–99.

A SAMPLE of so-called pure monobromobenzene, examined recently by the author, was found to have a somewhat wide range of boiling point, and to leave a crystalline residue when distilled to a temperature above the boiling point of the pure compound (155° C.). Another sample, also supposed to be pure, yielded fractions having very different boiling points. On re-distilling the fractions boiling between 153° and 159° C., a distillate boiling at 153°–154° C., and amounting to 80 per cent. of the volume of the original sample, was obtained. The lower-boiling fractions of the distillation contained unbrominated benzene, and a crystalline residue of dibromobenzene, amounting to about 3 per cent., remained in the distillation flask.—W. P. S.

Caffeine in coffee; Determining —. Lendrich and Notthohm. See XVIII.A.

Detecting glycerol. Denigès. See XII.

The sale of poisons. Times, April 1, 1909. [T.R.]

THE Poisons and Pharmacy Act, 1908, came into force on April 1st. The Privy Council has drafted regulations for the purpose of carrying Section II. into effect. This section empowers local authorities to grant licences under certain conditions to shopkeepers, other than registered chemists, to sell sheep dips, weed killers, insecticides, and the like. The draft regulations provide that in granting these new licences preference shall be given to nurserymen, florists, seedsmen, and other persons whose business is specially connected with horticulture. The local authority must be satisfied that the licensee is a fit and proper person to be entrusted with the sale of poisons. The licence is to be an annual one, the fee for which may not exceed 2s., and 2s. 6d. for renewal.

The regulations have not yet been approved, and in the meantime suggestions for their amendment have been submitted by various public bodies in the direction of making some provision for notification to the public of all applications for licences, and providing for the right of the general public to appear before the local authority with reference to the applications.

As regards Section V., by which, for the first time, conditions are made respecting the precautions which must be observed by retailers of sulphuric acid, nitric acid, hydrochloric acid, and the soluble salts of oxalic acid, the Privy Council is also empowered to make regulations other than those provided in the Act, but no further regulations have as yet been issued. The penalty for infringement of any of these provisions may not exceed £5.

PATENTS.

Sulphur compounds [Dithiodiglycollic acid, etc.]; Manufacture of —. T. S. Price, Birmingham. Eng. Pat. 9003, April 25, 1908.

DITHIODIGLYCOLLIC acid compounds or derivatives are prepared by subjecting to electrolysis the product of the reaction of a thiosulphate on a halogen acetic acid compound or derivative. Organic disulphides are prepared by treating a halogenised hydrocarbon or substituted derivative thereof with a thiosulphate, and subjecting the products to the action of an alkaline reagent. In particular, the *o*-, *m*-, and *p*-dinitrobenzyl disulphides are claimed, prepared by the action of sodium thiosulphate on the corresponding nitrobenzyl chlorides in dilute alcohol, and treating the products with sodium carbonate.—J. F. B.

Bacillus bulgaris culture; Method of preparing — for therapeutic purposes. C. Löloff, Breslau, Germany. Eng. Pat. 19059, April 25, 1908.

EIGHT parts of malt extract are dissolved in 92 parts of water, the solution is sterilised, cooled, and decanted from the sediment after the lapse of about 15 hours. The solution is filtered through a sterilised filter, again sterilised, and cooled to a temperature of about 45° C. The solution is then inoculated with a mixture of lactic acid bacilli, amongst which is contained *Bacillus bulgaris*, and the whole is kept at 45° C. for 15 hours. The *Bacillus bulgaris* develops rapidly, and prevents the other lactic acid bacilli from growing. The culture thus obtained is stored in small sterilised bottles.—W. P. S.

Salicylic acid derivatives; Manufacture of —. G. W. Johnson, London. From C. F. Boehringer und Söhne, Wadthof, Germany. Eng. Pat. 11,457, May 26, 1908.

WREN salicylic acid or one of its salts is treated with a condensing agent in quantity sufficient to split off only one molecule of water from two molecules of acid, salicylo-salicylic acid, $\text{C}_6\text{H}_4(\text{OH})\text{CO}_2\text{O}\text{C}_6\text{H}_4\text{COOH}$, is produced. This substance melts at 147–148° C., and crystallises from benzene in coarse crystals. It is soluble in hot alcohol and ether, and has therapeutic properties resembling those of salicylic acid. As condensing agents, phosphorus trichloride, phosphorus oxychloride, thionyl chloride, and others may be used.—F. SHOX.

Camphene; Process for preparing —. Act.-Ges. f. Anilinfabr. Ger. Pat. 206,386, Feb. 14, 1907.

GOOD yields of camphene are obtained by heating pinene hydrochloride with α - or β -naphthylamine at 180°—

200° C., for short periods, in open vessels. At higher temperatures the camphene produced is rapidly decomposed.—T. F. B.

Oxidation of organic compounds; Process for the — by means of compounds of nitric acid with aldehydes or ketones. A. A. Schukoff. Ger. Pat. 206,695, June 16, 1907.

THE compound to be oxidised is treated, at the ordinary temperature, or with moderate heating, with compounds of nitric acid with aldehydes or ketones, either alone or in presence of nitric acid. These compounds are prepared by dissolving the aldehyde or ketone (cinnamic aldehyde, camphor, menthone, benzaldehyde, acetophenone) in nitric acid, in molecular proportions or in presence of a slight excess of the acid, then cooling the solution, and separating the resulting crystals by suction.—A. S.

Cotarnine cholate; Process for preparing —. F. Hoffmann-La Roche und Co. Ger. Pat. 206,696, Sept. 29, 1907.

COTARNINE cholate is obtained by the interaction of molecular quantities of cotarnine and cholic acid in the cold, in presence of a suitable solvent such as water; it is readily soluble in water and alcohol, but insoluble in benzene and petroleum spirit. It melts at 118°–120° C., with decomposition.—T. F. B.

Bismuth salts of bromine substitution products of catechol; Process for preparing —. Chem. Fabr. von Heyden A.-G. Ger. Pat. 207,544, April 11, 1908.

THE bismuth salts of di-, tri-, or tetra-bromo-catechol are obtained by the usual methods for preparing organic salts; they are tasteless and odourless, and when taken internally, do not cause the burning sensation which is felt with the bismuth salt of tribromophenol (xeroform). All these compounds are for use as substitutes for iodoform.—T. F. B.

Hexamethylenetetramine and mercuric salts; Manufacture of soluble compounds of —. A. Busch, Brunswick, Germany. Eng. Pat. 4712, March 2, 1908.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

Photographic development; The retarding action of bromides on — as a colloid-chemical process. Lippocramer. Z. Chem. Ind. Kolloide, 1909, 4, 92—94.

WHEN over-exposed photographic plates are developed (with ferrous oxalate, glycin, metol, etc.) in presence of large quantities of soluble bromides, the resulting image is a clear grey in colour, instead of the normal black. If these negatives be fixed in solutions of silver bromide in sodium thiosulphate, to which potassium metasilphite has been added, the image is greyish white, whereas the image of a normally exposed plate, developed without the use of bromide, is black; the former is also much more readily dissolved by acid solutions of ammonium persulphate, the normal image being very slowly attacked. It is also found that silver bromide precipitated from aqueous solutions, when reduced with ferrous oxalate in presence of bromide, gives a brighter silver than when bromide is absent. These observations tend to show that the retarding action of bromides on development is a colloid-chemical rather than a purely chemical action. (See this J., 1908, 959, 1041).—T. F. B.

PATENTS.

Photo-engraving or photo-etching; Preparation of surfaces suitable for —. A. Payne, Whitley Bay. Eng. Pat. 28,415 of 1907. Date of application, June 22, 1908.

A METAL plate is coated with a protective layer of collodion, bitumen, resin, etc., and then with a sensitive emulsion. After exposure and development of the image, and reversal if necessary, the plate is treated with a solution of bichromate and washed, the exposed portions of the protective coating being then dissolved away. The plate is now ready for etching in the usual manner.—T. F. B.

Screens or coloured surfaces for colour photography; Manufacture of —. L. Dufay, Chantilly, France. Eng. Pat. 11,698, May 29, 1908. Under Int. Conv., June 4, 1907.

THREE bichromated gelatin films are exposed behind suitably ruled or dotted screens, developed, stained with the three colours desired for the ultimate screen, and then coated with some black fatty ink, which only adheres to the colourless portions of the films. A gelatin-coated surface is applied to one of these films, and the print is coated with an alcohol varnish; when the varnish is dry, the print is treated with a solvent, such as turpentine oil, which will remove the varnish-coated ink lines. The print will now consist of a series of coloured lines covered by varnish, and a series of transparent lines with no covering. It is then applied to each of the other films in the same way, and varnished as above, the lines in each case being at a suitable angle to the existing lines, so as to produce a three-colour screen, which is finally cleared of varnish.—T. F. B.

Toning reagents and processes for toning photographic prints. H. E. Smith, London. Eng. Pat. 12,341, June 6, 1908. Addition to Eng. Pat. 22,218, Oct. 8, 1907 (see this J., 1908, 1178).

PHOTOGRAPHIC prints on gelatino-chloride or albumin papers are fixed, with or without previous washing or treatment with salt solutions, in solutions of sodium thiosulphate, ammonia, or sodium sulphite, and then toned in solutions of thionolylates or thionogstates. They are then washed, and, if desired, treated with ammonia solution. The tones obtained are purple-brown to black.—T. F. B.

Photographic silver prints into pigment prints; Process for converting —. Neue Photographische Ges. Ger. Pat. 207,319, April 20, 1907.

SILVER bromide prints are coated with a layer of pigmented gelatin, and the resulting sheet is treated with a solution of an alkali bichromate and ferricyanide and potassium

bromide, when it can be developed (see Eng. Pat. 17,067 of 1905; this J., 1906, 655). The silver print can be coated with the pigmented gelatin before fixation, in which case the silver is dissolved out of the combined film after the treatment. If desired, the gelatin may be pigmented in differently coloured areas, so as to give a print in several colours.—T. F. B.

XXII.—EXPLOSIVES, MATCHES, &c.

Cellulose and nitrocellulose from Agave. A. Carneiro. Z. ges. Schiess- und Sprengstoffwesen, 1909, 4, 103—105.

ANALYSES are given of fibres obtained from the flower stem of various species of *Agave*. The cellulose content varied from 71.4 to 80.6 per cent., and the ash from 2.64 to 2.80 per cent. Samples of the fibre were finely divided, purified by boiling with sodium carbonate, and then bleached. The dried material was nitrated with acid mixtures, consisting of strong sulphuric acid and nitric acid in proportions varying from equal quantities of these acids to from 2 to 3 parts of sulphuric acid and 1 part of nitric acid. The nitrogen content of the resulting nitrocellulose varied from 11.5 to 12.4 per cent.

—G. W. McD.

Detecting and determining chlorates. Virgili. See VII.

PATENTS.

Explosive compound and process of producing the same. G. Izinsky, New York. U.S. Pat. 909,915, Jan. 19, 1909.

A FINELY powdered mixture of about 2 parts of rosin and 1—3 parts of a cereal, such as wheat, is mixed with just sufficient nitric acid of 36°—42° B. to yield a porous cake, which is dried and finely pulverised. If necessary the reaction is started by the application of heat. To one part of this nitrated product, which is non-explosive, and contains 20—50 per cent. of matter soluble in water, 3 parts of potassium chlorate are added, and sufficient water to form a homogeneous mixture, which is moulded into sticks, cakes, grains, or the like, and then dried. As the product is not resistant to water, the dried sticks, etc., are coated with paraffin wax or similar substance.

—A. S.

Explosives; Manufacture of —. W. H. Palmer. Fr. Pat. 394,833, Oct. 2, 1908.

THE claim is for a non-hygroscopic, stable, powerful, and rapid explosive suitable for use in mines, containing 50 per cent. of ammonium perchlorate, 14 of dinitrotoluene, 31 of sodium nitrate, 5 of aluminium powder, and 5 per cent. of paraffin wax of melting point not less than 48° C. The sodium nitrate may be replaced by an equivalent quantity of potassium nitrate. The proportions of the ingredients may be varied, but those given are recommended. The rapidity of action may be increased by adding a small quantity of charcoal.—J. W. G.

Matches; Process whereby oily or resinous woods or those having a close texture may be used in the manufacture of —. A. Thielenberg. Fr. Pat. 394,870, Sept. 26, 1908.

It is proposed to treat woods, that are unsuited for direct impregnation with paraffin, by immersing the splints held by their "head" ends in alkaline, acid, or other baths of a kind and strength determined by the kind of wood. It is claimed that by this means the wood is freed from resinous matter and softened.—J. W. G.

Gunpowder. C. P. H. Claessen, Berlin. U.S. Pat. 914,113, March 2, 1909.

SEE Addition of Aug. 30, 1906, to Fr. Pat. 364,413 of 1906; this J., 1907, 167.—T. F. B.

Treating cellulose. Berl. See XIX.

XXIII.—ANALYTICAL CHEMISTRY.

APPARATUS.

Quartz combustion tubes; Use of — especially for the direct determination of carbon in steel. B. Blount and A. G. Levy. Analyst., 1909, 34, 88—95.

TUBES of clear quartz (silica) were found to be well-suited for use in organic combustions, and to be much longer-lived than glass tubes. Silica withstands the action of copper oxide, lead chromate, etc., very well unless the temperature be excessive; at about 900° C., however, copper oxide attacks and destroys quartz tubes. The tubes are also suitable for the determination of oxygen in copper by fusion in hydrogen; the authors heat the tube electrically by passing a current of suitable strength through a long strip of platinum, or iridium-platinum, which is wound round the tube and surrounded by a coating of asbestos cloth. For the determination of carbon in steel, the quartz tube was surrounded by two separate sections of stout iridium-platinum foil at a short distance from each other, each section being enclosed in two fireclay semi-cylinders which, in turn, were covered with asbestos cloth. The sections were so wired, that the current could be passed through either section, or both. The steel to be analysed was placed in a boat surrounded by a piece of iridium-platinum foil rolled into the form of a tube in order to prevent injury to the quartz by the sparks of oxidised metal. The boat itself was protected from the action of the burning steel by placing a layer of ignited alumina in the bottom. Since steel, when burning in oxygen, suddenly absorbs a large quantity of oxygen, means have to be provided for supplying a sufficient quantity of the gas at the moment that it is required. For this purpose, the supply of oxygen to the combustion tube is passed through a Y-tube, one arm of which communicates through a trap with the open air. The oxygen is passed into the tube at such a rate, that, before the steel begins to burn, a portion escapes into the air, the rate of the gas passing through the potash bulbs at the other end of the combustion tube being controlled by the action of an exhaust pump. When the steel burns, the escape of oxygen into the air ceases, and air itself is drawn into the combustion tube, mixing with the oxygen and passing through the same purifying apparatus. The oxidation of the carbon monoxide evolved during the combustion, is effected by packing the exit end of the combustion tube with a mixture of platinised quartz and platinum scrap, and a supplementary supply of oxygen is admitted to this end of the tube through a side tube which ends just in front of the oxidising mass. A piece of silver foil, placed just before the boat, protects the rubber stopper from the intense radiation characteristic of quartz tubes. The results obtained agree well with each other, and differ by less than 0.02 per cent. from those given by the solution method.—W. P. S.

Nickel crucible for the determination of carbon in steel. H. E. K. Ruppel. J. Ind. and Eng. Chem., 1909, 1, 184—187.

THE author recommends the use of a nickel crucible instead of a platinum one. The crucible described, is of a somewhat similar kind to the platinum crucible of Shimer (see this J., 1899, 863), being provided with a water-cooled bronze cover and a separate bronze water-jacket round its upper part. The results obtained agree closely with those obtained by use of a platinum crucible.—A. S.

Silver; Determination of — as silver chromate. F. A. Gooch and R. S. Bosworth. Amer. J. Sci., 1909, 27, 241—244.

THE authors have shown previously (this J., 1908, 838) that chromium may be determined as silver chromate, and they now give the conditions under which silver is precipitated quantitatively, as silver chromate, from its solutions.

By adding potassium chromate solution to silver nitrate solution, and boiling the mixture, the silver is precipitated completely; the precipitate may be collected on a filter directly, or dissolved in ammonia, and re-precipitated by evaporating the solution to a volume of about 15 c.c. This treatment yields a crystalline precipitate which filters readily. In either case, the precipitate is washed first with dilute potassium chromate solution, and then with the minimum quantity of water, before being dried and weighed. Potassium bichromate cannot be used as the precipitant, as a small proportion of the silver present remains in solution. Should the silver nitrate solution contain free nitric acid, sufficient potassium chromate must be added to take up the nitric acid with formation of bichromate, as well as to form the silver salt.—W. P. S.

Uranium; Speed of oxidation, by air, of uranous solutions, with a note on the volumetric determination of —.
H. N. McCoy and H. H. Bunzel. *J. Amer. Chem. Soc.*, 1909, **31**, 367—373.

THE simplest volumetric method for the determination of uranium, is to convert the uranium into uranyl sulphate, reduce it with zinc and sulphuric acid to uranous sulphate, and titrate with standard potassium permanganate. The determination is, however, complicated by the rapidity with which uranous solutions oxidise in air and by the fact that the reduction with zinc and sulphuric acid generally goes somewhat beyond the uranous stage, 1 or more per cent. being reduced to the tervalent form. It was found that the over-reduced uranium was very rapidly oxidised by air to the uranous state, but further oxidation proceeded at a slower rate and was greatly retarded by the presence of an excess of sulphuric acid. In ordinary practice the amount of sulphuric acid in the reduced solution, diluted with the wash water, is equivalent to about 1.5N. At 25° C. such a solution, saturated with air, would oxidise at the rate of about 0.3 per cent. per minute. If, however, 3N-sulphuric acid be used instead of water to wash the zinc and to dilute the solution, the oxidation of the uranous salt by the air is practically negligible, while the over-reduced salt is entirely converted by the air into the uranous condition. The separation of uranium from the elements which usually accompany it in minerals is probably best accomplished by precipitating it as phosphate.
—F. R.

Thallium; Volumetric determination of —. W. J. Müller. *Chem.-Zeit.*, 1909, **33**, 297—298.

THE author shows that thallium can be determined volumetrically with great accuracy by a combination of two previously suggested methods. The solution containing the thallium in the thallous condition is first titrated with permanganate in presence of hydrochloric acid according to Wilm's method (see Marshall, this J., 1900, 994). Either the permanganate must be standardised with metallic thallium, or 0.4 per cent. must be deducted from the result to compensate for the action of the hydrochloric acid on the permanganate (compare this J., 1908, 247), if the latter has been standardised with oxalic acid. After the titration, the solution is boiled to destroy the excess of permanganate, and the thallium determined iodometrically by the method of Thomas (this J., 1902, 501), the titration with permanganate replacing the oxidation with potassium chlorate and hydrochloric acid described by that author. The percentage of thallium is taken as the mean of the values obtained in the two titrations.—A. S.

Phosphoric acid; Estimation [Determination] of — [in urine]. R. Weiss. London. Eng. Pat. 9725, May 5, 1908.

TEN c.c. of the urine and 3 c.c. of "ammonia-magnesia" solution are mixed in a tube, and the volume of the precipitate formed is read off at the end of 24 hours, one end of the tube being narrow and graduated for this purpose. The volume of the precipitate is a measure of the phosphoric acid in the urine.—W. P. S.

ORGANIC—QUALITATIVE.

Reducing sugars; Reagent for the detection of —. S. R. Benedict. *J. Biol. Chem.*, 1909, **5**, 485—487.

It has been shown that for the detection of dextrose a copper solution which is made alkaline with sodium carbonate is more delicate and specific than the solutions more generally used containing sodium hydroxide. The reagent of this nature previously suggested (this J., 1907, 1102), containing copper sulphate, Rochelle salt, and sodium carbonate, is highly satisfactory when fresh, but rapidly deteriorates and becomes useless. This fault has been overcome by using a solution containing 17.3 grms. of copper sulphate, 173 grms. of sodium citrate, and 100 grms. of sodium carbonate (anhydrous), with distilled water to make 1000 c.c. This reagent is more sensitive to dextrose, either in pure solution or in urine, than Fehling's solution and is not reduced by uric acid. It is also highly permanent, as samples of the solution kept for a year in partially filled bottles, exposed to light and heat, had not suffered spontaneous reduction nor were they reduced on being heated for 24 hours in a bath of boiling water. Freshly prepared Fehling's solution on being heated in the same way showed a marked precipitation in three hours, and the precipitate increased with further heating. Since the new solution contains no strongly dehydrating agent, the reduction product is frequently yellow or green, rather than red, as in Fehling's test. The solution is used in the same way as Fehling's solution, but it is desirable to boil for from one to two minutes and then allow the tube to cool.

XXIV.—SCIENTIFIC & TECHNICAL NOTES.

Chemical change; Influence of moisture on —. H. B. Baker. *Chem. News.*, 1909, **99**, 126—127.

A SUMMARY is given of the chemical actions which have been shown to be dependent on the presence of moisture. Ionisation is also effective in causing chemical action. Mercury vapour under ordinary conditions contains only

atoms which exhibit little tendency to combine with oxygen. In the mercury vapour lamp, however, the mercury vapour is ionised, and when the current is cut off and oxygen admitted, the mercury becomes covered with a layer of mercuric oxide. This ionisation is regarded as the splitting off of an electron from the atom as distinct from a molecule and the charged atom then enters into union with oxygen. The combustions of carbon bisulphide and of cyanogen in oxygen which are apparently unaffected by the absence of moisture are due to the formation of charged atoms capable of direct union with oxygen when these gases are heated, both being readily broken up into their elements. Radium bromide which is able to produce ionisation in very dry air does not cause chemical action between mixtures of hydrogen and oxygen or carbon monoxide and oxygen. Hence ionisation cannot of itself produce chemical action, though it can increase the rate of union of two gases under conditions which would otherwise produce a slow chemical action. The reaction between nitrous oxide and hydrogen at 530° C. in presence of moisture, is quickened by the presence of lime, more so by the presence of thoria, while the gases in contact with radium bromide combine with explosion. In the absence of moisture, increasing the ionisation has no effect. The same gases dried in a tube containing thoria showed no combination when heated. When a small open tube of radium bromide was placed in a mixture of sulphur dioxide and sulphuretted hydrogen, the whole of the gases condensed in the tube in the form of sulphur and water. What happens is that the water vapour condenses in liquid drops on the ionised particles in the radium tube, and in these drops the reaction between the two gases is completed. In the other chemical changes at high temperatures, it is conceivable that condensation to some form approaching the liquid state might take place. If action is to take place, ions and water vapour (or some similar substance) must both be present in a mixture of gases.—E. F. A.

Crystallisation; Spontaneous——R. Marcelin. *Compt. rend.*, 1909, **148**, 631—633.

WHEN the temperature of a superfused liquid is decreased sufficiently, a certain number of centres of crystallisation are spontaneously formed at different points in the liquid. The spontaneous power of crystallisation is defined by the number of nuclei formed in unit time in unit volume. From a large number of experiments on lead acetate, the author concludes that, other things being equal, (1), the power of spontaneous crystallisation decreases with the total period during which the substance has been kept in the liquid state, but is independent of the number of crystallisations which divide this total period of fusion; (2), this power decreases with increase of the temperature at which the liquid has been maintained. The author ascribes the phenomena observed in respect of spontaneous crystallisation to the presence of suspended foreign particles (which undergo coagulation or the reverse process during fusion) on which the nuclei are formed. In certain cases he has observed particles at the centre of crystallisation, and he has also found that filtration decreases the number of nuclei, and that addition of particles of foreign matter increases them. Powdered zinc oxide, powdered manganese dioxide, and especially spongy platinum, inhibit supersaturation very strongly, whereas mercury, platinum in the massive state, and wood charcoal, have little effect; it appears therefore, that the added substance is more active in the powdered form (large surface and high curvature), than in mass. If crystals possess capillary tension, spontaneous crystallisation must be regarded as being very closely related to the condensation of vapours; the suspended foreign particles produce a true physical catalysis, the mechanism of which is probably explained by the theory of capillarity. Particles of gamboge which do not coagulate in potassium nitrate solution (and which, therefore, possess a low capillary constant in this medium) do not inhibit the supersaturation of this salt; colloidal silver, on the other hand, which does coagulate, inhibits supersaturation.—L. E.

Tyrosinase. A. Bach. *Ber.*, 1909, **42**, 594—601.

THE oxidising action of oxydases or the system, peroxydase hydrogen peroxide, is non-specific; it does not depend on the nature of the body oxidised, but merely on the presence of labile hydrogen groups. Tyrosine is not oxidised by such agents, but requires a specific ferment, tyrosinase. In order to explain this peculiarity, Gonnermann has suggested that tyrosinase is primarily not an oxidising, but a hydrolytic enzyme, and that the tyrosine is converted under its action into products of hydrolysis which are readily oxidisable (this *J.*, 1900, 1125). The author has tested this hypothesis in several ways but finds it quite untenable. Previous digestion of tyrosine, whether by tyrosinase in absence of air or by trypsin, had no effect on the specific reaction. Neither were synthetic mixtures of the possible products of hydrolysis of tyrosine affected by tyrosinase in such a way as to yield the characteristic black oxidation product. The author finds that in no case does tyrosine undergo the characteristic oxidation, whether in presence of peroxydase, hydrogen peroxide, or a plant extract, unless active tyrosinase be present. A purified neutral preparation of a peroxydase, with or without hydrogen peroxide, has a retarding influence on the oxidation of tyrosine by purified tyrosinase; this fact was established by quantitative determination, by the permanganate method. If the plant-extract or tyrosinase preparation contain a reducing or other inhibitive substance, the presence of peroxydase and hydrogen peroxide may produce a temporary accelerative effect on the oxidation, but subsequently the retarding influence of the peroxydase is manifested. Thus the action of tyrosinase is of a very different order from that of ordinary oxydases. Tyrosinase apparently belongs to a special class of oxidising ferments the oxidising action of which extends to bodies with less labile hydrogen groups.—J. F. B.

Chloralic acids. M. Hanriot. *Compt. rend.*, 1909, **148**, 487—489. (See also this *J.*, 1893, 372; 1894, 755).

THE author has already described, under the name of chloraloses, the compounds which he has obtained by the action of chloral on various hexoses and pentoses, and has shown that they correspond to formulae such as the following:—

Two isomeric chloraloses are formed in the reaction and the author has isolated them in most cases. He now describes the following chloralic acids, obtained by oxidising the chloraloses with (1) potassium permanganate and sulphuric acid, (2) nitric acid:— α - and β -Dextrochloralic-, β -galactochloralic-, α - and β -arabinochloralic-, and β -xylochloralic acids. All these acids contain seven atoms of carbon; hence, in the case of the hexochloraloses, an atom of carbon must be split off in the form of carbon dioxide during oxidation. These acids should have the following constitution:—

β -Dextrochloralic and xylochloralic acids are identical, and the same applies to galactochloralic and β -arabinochloralic acids. The chloralic acid derived from mannose is immediately converted into the lactone when liberated from its salts, and unlike the above-mentioned acids, mannochloralic lactone contains eight atoms of carbon; it may be that the immediate formation of lactone, protects the side chain against further oxidation.—L. E.

Sugars; New method for determining the constitution of the —. M. Hanriot. Compt. rend., 1909, 148, 640—643. (See preceding abstract.)

THE stereoisomerism of the chloralic acids, apart from that due to the OHCH-group (which is derived from the aldehyde group of the sugar, and the isomerism of which is responsible for the existence of α - and β -chloraloses and chloralic acids) must be due to the 3 carbon atoms derived from the 3 CHOH-groups, adjacent to the aldehyde group in the original sugar. The sugars in question may be classified thus:—

In these formulæ, R represents a CH_2OH -group in C_5 -sugars, and a $\text{CHOH}-\text{CH}_2\text{OH}$ group in C_6 -sugars. The sugars belonging to any one group should give the same chloralic acid; the author has verified this for dextro- and xylochloralic acids (group I.) and for galacto- and arabinochloralic acids (group II.). The constitution of an aldopentose or aldohexose may thus be determined completely or partially. The sugar is combined with chloral, and the less soluble chloralose isolated; if this is identical with a chloralose already known, the question is determined. If the sugar is a new one, an examination of the chloralic acid derived from it, will show to which of the above groups the sugar belongs; this suffices to identify an aldopentose, and in the case of an aldohexose the choice is limited to two isomerides. For the identification of ketoses the method does not appear to be of much value.—L. E.

Cellobiose and its osone; Behaviour of — towards some enzymes. E. Fischer and G. Zemplen. Annalen, 1909, 365, 1—6.

THE authors have found that cellobiose (this J., 1902, 144), a disaccharide of dextrose, is easily hydrolysed by emulsin, but is not attacked by yeast extract, and thus resembles gentiobiose (*ibid.*, 1902, 1251) and isomaltose (*ibid.*, 1905, 1246), and somewhat resembles lactose. These results indicate that cellobiose, gentiobiose, and isomaltose possess the same configuration in respect of the coupling of the two dextrose residues, whilst maltose differs from them. If emulsin which decomposes β -glucosides, be assumed to be a specific reagent for the β -configuration, the three disaccharides decomposed by it may be regarded as dextrose- β -glucosides. The authors point out, however, that this assumption must not be regarded as beyond doubt; it involves the supposition that the same enzyme hydrolyses both alcohol-glucosides and dextrose-glucosides, and this cannot be proved by the use of complicated mixtures such as emulsin or yeast extract. Cellobiose is not hydrolysed by either extract of *Aspergillus niger*, or Kephir lactase. The authors prepared cellobiosone by a method previously described (Ber., 1902, 3141; this J., 1902, 1302); this compound is hydrolysed by emulsin to dextrose and dextrosone.—L. E.

Imperial College of Science and Technology. Times, April 5, 1909. [T.R.]

At a meeting of the governors of the Imperial College, held on April 2, it was decided, subject to the approval of the King in Council, to recognise the metallurgical department of the University of Sheffield as being in association with the Imperial College of Science and Technology for the advanced metallurgy of iron and steel, as provided for in the charter, Article V. The architect was instructed to prepare the necessary plans and quantities and to obtain tenders for the new building for mining, metallurgy, and geology to be erected in Prince Consort Road, and also to prepare plans for the extension of the engineering departments of the City and Guilds College in Exhibition

Road and Prince Consort Road. The erection of the new mining building is expected to begin almost at once, and steps are being taken in connection with the foundation-stone ceremonial.

Trade Report.

Mineral production of Canada in 1908. Eng. and Mining J., Mar. 13, 1909.

Product.	Quantity.	Value.
METALLIC.		
Copper	Lb. 64,361,636	\$8,500,885
Gold	Lb. —	9,550,274
Pig iron from Canadian ore	Tons. 99,420	1,664,302
Lead	Lb. 45,725,886	1,920,487
Nickel	Lb. 19,143,111	8,231,538
Cobalt	Lb. 1,853,286	112,253
Silver	Oz. 22,070,212	11,667,197
Total value, metallic	—	\$41,655,936
NON-METALLIC.		
Arsenic	Tons. 699	38,054
Asbestos	Tons. 65,534	2,547,507
Asbestic and asbestic sand	Tons. 25,239	25,829
Calcium carbide	Tons. 6,864	417,150
Chromite	Tons. 7,225	82,008
Coal	Tons. 10,904,466	25,567,235
Corundum	Tons. 1,039	100,389
Felspar	Tons. 7,877	21,099
Graphite	Tons. 251	5,565
Grindstones	Tons. 3,843	45,128
Gypsum	Tons. 340,964	575,701
Limestone for flux in iron furnaces	Tons. 418,661	289,705
Magnesite	Tons. 120	840
Mica	Tons. —	101,602
Mineral pigments—		
Barytes	Tons. 4,091	18,265
Ochres	Tons. 4,746	30,440
Mineral waters	Tons. —	109,391
Natural gas	Tons. —	1,012,080
Petroleum	Bbl. 527,987	747,102
Phosphate (apatite)	Tons. 1,596	14,794
Pyrites	Tons. 47,336	224,824
Quartz	Tons. 27,134	32,277
Salt	Tons. 79,975	378,798
Talc	Tons. 1,076	3,048
Tripolite	Tons. 30	195
Total value, non-metallic	—	\$2,479,006
STRUCTURAL MATERIAL AND CLAY PRODUCTS.		
Cement, natural	Brls. 1,044	815
Cement, Portland	Brls. 2,665,289	3,709,063
Flagstones	No. 4,000	3,600
Sand and gravel (exports)	Tons. 298,954	161,387
Sewer pipe	—	514,042
Clay products, stone, lime, &c., est.	—	8,500,000
Total structural and clay products ..	—	\$12,888,967
Estimated value of mineral products not reported	—	300,000
Total value, 1908	—	\$87,323,849

Mineral production of the United Kingdom in 1908. Bd. of Tr. J., Mar. 18, 1909.

I.—Output of minerals under the Coal Mines Regulation Acts.

	1907.	1908.
	Tons.	Tons.
Barium (compounds)	10,297	5,217
Coal	267,812,852	261,506,370
Clay and shale other than fire-clay and oil shale	320,989	292,981
Fire-clay	2,890,097	2,814,411
Igneous rock	146	404
Iron pyrites	7,394	7,212
Ironstone	8,236,118	7,890,814
Limestone	22,366	15,416
Oil shale	2,675,779	2,891,564
Sandstone (including "ganister") ..	128,103*	110,513*
Total	282,104,141	275,534,911

* The quantity of ganister obtained was 120,193 tons in 1907 and 106,477 tons in 1908.

II.—Output of minerals under the Metalliferous Mines Regulation Acts.

	1907.	1908.
	Tons.	Tons.
Barium (compounds)	30,343	32,074
Clay and shale	114,525	123,911
Gold ore	12,978	7,123
Gypsum	198,919	190,497
Igneous rock	69,871	67,627
Iron ore	1,802,946	1,549,469
Lead ore	31,304	29,097
Limestone	470,263*	500,517*
Rock salt	216,020	209,904
Sandstone	156,324†	195,568†
Slate	116,570	104,050
Zinc ore	20,082	15,189
Other minerals	117,819	99,371
Total	3,388,924	3,124,397

* Including 8,363 tons of calc spar in 1907 and 2,655 tons in 1908.

† Including 11,864 tons of ganister in 1907 and 7,922 tons in 1908.

The above figures do not represent the total production of the minerals. Large quantities of several important minerals, such as iron ore, limestone, sandstone, slate, clay, &c., are obtained from quarries under the Quarries Act and from other open workings, the returns from which are not yet available. The totals for coal, and the ores of copper, lead, and zinc may, however, be regarded as substantially complete.

New Book.

TABLES OF CASES OF INDUSTRIAL POISONING, FATAL AND NON-FATAL ACCIDENTS, AND DANGEROUS OCCURRENCES IN FACTORIES, WORKSHOPS, ETC., DURING 1908. [Cd. 4518.] Wyman and Sons, Fetter Lane, London, E.C. Price 1d.

THESE tables show the number of cases of poisoning, accidents, etc., which occurred in premises under the Factory and Workshop Act, during 1908. The total number of cases of poisoning was 727, and 40 deaths from poisoning are recorded: The figures for 1907 were 653 and 40 respectively. In 1908, there were 646 cases of lead poisoning, 10 due to mercury, 1 to phosphorus, and 23 to arsenic. With regard to fatal accidents, 23 occurred in the printing, dyeing, and bleaching industries; 6 in connection with glass; 45 in chemical industries, and 3 from explosives.

Patent List.

Where a Complete Specification accompanies an Application, an asterisk is affixed. The dates given are (i) in the case of Applications for Patents, the dates of Application, and (ii) in the case of Complete Specifications Accepted, those of the Official Journals in which acceptances of the Complete Specifications are advertised.

Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

I.—PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

6211. Martin. Filter presses and the like. March 16.
 6277. Wiart. Automatically superheating vapours. [Fr. Appl., March 16, 1908.]* March 16.
 6408. Boulton (Egyetemes Kiserlető Intézet Vegyészeti Orvosi). Lixivating crystalloids from parts of plants and other organic substances.* March 17.
 6533. Dieker (Oesterr. Chem. Werke, and Löwenstein). Fractional condensation of vapours.* March 18.
 6557. Kirkham, Hulett, and Chandler, Ltd., and Blake. Apparatus for cooling and condensing gases, vapours, etc. March 18.
 7154. Wiegand. Evaporating apparatus. March 25.
 7185. Kamm. Charging cylinders or steel bottles with oxygen and other gases. March 25.

COMPLETE SPECIFICATIONS ACCEPTED.

- 5969 (1908). Cottrell. Separating suspended particles from gaseous bodies. March 24.
 6036 (1908). Boulton (D'Arloux). Tunnel kilns. March 24.
 17,589 (1908). Langlet and Rinman. Method of producing pulverulent precipitates. March 31.
 18,956 (1908). Bromham. Centrifugal drying machines. March 24.
 27,473 (1908). Pauling. Simultaneously distilling and concentrating liquid mixtures. March 31.

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

6163. Morris. Manufacture of artificial fuel. March 15.
 6167. Ernst. Cleaning gases. [U.S. Appl., April 15, 1908.]* March 15.
 6181. Jarrett (Graf). Manufacture of gas. March 15.
 6196. Harrop and Soper. Manufacture of incandescent gas mantles. March 16.
 6279. Zirfas. Coke ovens. March 16.
 6515. Schmidt. Purification of gases.* March 18.
 6556. Muller and Bonnet. Manufacture of incandescent gas mantles. [Fr. Appl., March 20, 1908.]* March 18.
 6845. Von Bauer. Coke ovens. [Comprised in No. 6575, March 24, 1908.] March 22.
 6936. Westinghouse Metal Filament Lamp Co. (Lederer). Manufacture of metallic filaments for incandescent electric lamps. March 23.
 7092. Heinrich. Manufacture of non-carbon incandescent filaments from refractory metals or their compounds.* March 24.
 7400. Gower. Production of semi-water gas. March 27.

COMPLETE SPECIFICATIONS ACCEPTED.

- 6191 (1908). King and Workman. Gas producer plant. March 24.
 6204 (1908). Stewart. Gas producers. March 24.
 6223 (1908). Coke-Ovens and By-Products Co., and Wellington. Coke ovens. March 31.
 13,753 (1908). Jabs. Gas producers. March 24.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, PETROLEUM, AND MINERAL WAXES.

APPLICATION.

7427. Coulson. Treatment of tar.* March 27.

COMPLETE SPECIFICATION ACCEPTED.

- 22,122 (1908). Thompson (Lingner). Manufacture of water-soluble compounds of the condensation products of wood tar and formaldehyde. March 31.

IV.—COLOURING MATTERS AND DYESTUFFS.

APPLICATIONS.

- 6270 and 6272. Chem. Fabr. vorm. Sandoz. Manufacture of blue to violet dyestuffs of the gallocyanine series. [Ger. Appls., Sept. 24 and Oct. 31, 1908.]* March 16.
 6727. Bloxam (Act.-Ges. f. Anilinfabr.). Manufacture of a monoazo dyestuff for chrome-mordanted wool. March 20.
 6728. Bloxam (Act.-Ges. f. Anilinfabr.). Manufacture of yellow mono-azo dyestuffs. March 20.
 6831. Newton (Bayer and Co.). Manufacture of 1,8-diaminonaphthalene-4-sulphonic acid. March 22.
 6991. Johnson (Badische Anilin und Soda Fabrik). Manufacture of substituted phenylglycino-o-carboxylic acid compounds. March 23.
 6992. Johnson (Badische Anilin und Soda Fabrik). Manufacture of halogenated indigo colouring matters. March 23.

COMPLETE SPECIFICATIONS ACCEPTED.

- 11,867 (1908). Newton (Bayer und Co.). Manufacture of a sulphonic acid of celestine blue. March 24.

15,352 (1908). Imray (Soc. Chem. Ind. in Basle). Manufacture of permanent printing colours and their application in printing fabrics. March 24.

25,311 (1908). Johnson (Badische Anilin und Soda Fabrik). Manufacture of azo colouring matters. March 31.

V.—PREPARING, BLEACHING, DYEING, PRINTING, AND FINISHING TEXTILES, YARNS, AND FIBRES.

APPLICATIONS.

6486. Dean. Vats for dyeing and like purposes.* March 18.

6876. Meister, Lucius, and Brüning. Production of colour effects on textile fabrics. [Ger. Appl., March 27, 1908.]* March 22.

6975. Warburton. Appliances for bleaching or dyeing yarn in the cop, cheese, or other dense form. March 23.

7129. Castle. Material for use in textile and other manufactures. March 24.

COMPLETE SPECIFICATIONS ACCEPTED.

7605 (1908). Matter. Removal of lye from textile materials. March 31.

9432 (1908). Hall. Machines for scouring, bleaching, and dyeing fibrous materials. March 31.

12,416 (1908). Johnson (Badische Anilin und Soda Fabrik). Production of white or coloured resist effects on textile fibre. March 24.

13,020 (1908). Hart. Rendering ramie and other fabrics water-repellent and permanently colouring them. March 31.

14,337 (1908). Johnson (Badische Anilin und Soda Fabrik). Bowking material which has been dyed or printed with vat dyestuffs. March 24.

15,009 (1908). Vidal. *See under XIV.*

15,352 (1908). Imray (Soc. Chem. Ind. in Basle). *See under IV.*

19,216 (1908). Siefert-Schwab. Printing fabrics. March 24.

22,549 (1908). Bloxam (Chem. Fabr. Griesheim Elektron). Reserving woollen threads in dyeing union goods with sulphurised dyestuffs. March 31.

270 (1909). Cassella und Co. Dyeing union fabrics. March 24.

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

6115. Peniakoff. Manufacture of bicarbonate of soda. March 15.

6294. Freeth. Manufacture of ammonium nitrate. March 16.

6411. Jones. Purifying and revivifying spent or waste lime.* March 17.

6415. Mackenzie. Concentration of sulphuric acid and apparatus therefor.* March 17.

6822. Pearlman and Pearlman. Recovering zinc compounds and ammonia.* March 22.

7125. International Salt Co., Ltd., and Tee. Purification or treatment of sodium nitrate or potassium nitrate. March 24.

7307. Sinding-Larsen and Ellestad. Manufacture of silicon nitride. [Appl. in Norway, March 27, 1908.]* March 26.

COMPLETE SPECIFICATION ACCEPTED.

22,029 (1908). Berry. Process for obtaining tartaric acid. March 31.

VIII.—GLASS, POTTERY, AND ENAMELS.

APPLICATIONS.

6195. Higginbottom. *See under IX.*

6560. Weber. Manufacture of liquefiable masses from clays, porcelains, etc.* March 18.

6573. Boosé (Stern and Boosé). *See under XIII.A.*

7112. British Thomson-Houston Co. (General Electric Co.). Apparatus for treating refractory materials. March 24.

7293. Klein (Dard). System for disintegrating and cleansing clay, kaolin, etc. March 26.

COMPLETE SPECIFICATIONS ACCEPTED.

8049 (1908). Ford and Hill. Decoration of pottery, earthenware, china, etc. March 24.

23,968 (1908). Imray (Window Glass Machine Co.). Drawing glass. March 24.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

6195. Higginbottom. Treatment of cements, china clay, earths, ores, etc., in a granular form. March 16.

6299. Berglund. Manufacture of fireproof stone.* March 16.

6315. Cartwright and Cartwright. Artificial stone. March 16.

7197. Brearley and Moorwood. Manufacture of silica bricks and ganister. [Addition to No. 14,619 of 1908.]* March 25.

COMPLETE SPECIFICATION ACCEPTED.

15,556 (1908). Polifka and Hacker. Impregnation of wood. March 24.

X.—METALS AND METALLURGY.

APPLICATIONS.

6138. Steinweg. Soldering aluminium and metals rich in aluminium.* March 15.

6195. Higginbottom. *See under IX.*

6276. Norddeuts. Affinerie A.-G. Refining gold or gold alloys. [Ger. Appl., Sept. 21, 1908.]* March 16.

6461. Osborne and Carnegie. Apparatus for extracting sulphur dioxide and other gases from metal melting furnaces. March 18.

6529. Ruthenburg. Treatment of manganese and chromium ores containing iron.* March 18.

6684. Potter. Manufacture of nut iron, steel, or other metals. March 20.

6821. Reid. Separating and refining metals.* March 22.

6898. Batchelor and Batchelor. Detinning tin plate. March 23.

6993. Johnson (Chem. Fabr. Griesheim Elektron). Magnesium castings. March 23.

7014. Angel. Reduction of complex sulphide and other ores. March 24.

7101. Ford. Extraction of gold. March 24.

7340. Bennett. Apparatus for distilling mercury from gold amalgam. March 26.

7432. Ashcroft. Manufacture of aluminium.* March 27.

COMPLETE SPECIFICATIONS ACCEPTED.

5841 (1908). Sébillot and Maclaure. Extraction of gold from its ores. March 24.

6511 (1908). Hommel, and Metals Extraction Corporation. Treatment of sulphide ores or products. March 31.

15,192 (1908). Von Zelewski. Mechanical roasting furnaces. March 31.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

APPLICATIONS.

6278. Marriott and Grover. Electric insulating and waterproofing compositions. March 16.

6398. British Thomson-Houston Co. (General Electric Co.). Manufacture of refractory electric conductors. March 17.

6820. Reid. Electric furnaces. [U.S. Appl., Aug. 22, 1908.]* March 22.

6872. British Thomson-Houston Co. (General Electric Co.). Electrolytic cells. March 22.

7338. Nya Ackumulator Aktiebelaget Jungner, and others. Active mass for electrodes of elements with alkaline electrolyte.* March 26.

7396. Grunwald. Electric induction furnaces. [Ger. Appl., Aug. 15, 1908.]* March 27.

XII.—FATTY OILS, FATS, WAXES, AND SOAPS.

APPLICATION.

6934. Kayser. Detergent compositions.* March 23.

COMPLETE SPECIFICATION ACCEPTED.

6304 (1908). Irving. Manufacture of washing compounds or soaps. March 24.

XIII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, &c.

(A.)—PIGMENTS, PAINTS.

APPLICATIONS.

6531. Ely and Rollason. Manufacture of carbon. March 18.

6573. Boosé (Stern and Boosé). Manufacture of metallic paints and enamels from ores. March 19.

COMPLETE SPECIFICATION ACCEPTED.

14,338 (1908). Johnson (Badische Anilin und Soda Fabrik). Production of pigments. March 24.

(B.)—RESINS, VARNISHES.

APPLICATION.

6917. Johnson. Purification or refinement of gums, gum resins, resins, and balsams. March 23.

COMPLETE SPECIFICATION ACCEPTED.

23,429 (1908). Marks (Suter). Varnish and its manufacture. March 31.

(C.)—INDIA-RUBBER.

APPLICATIONS.

7302. Soc. Franç. de la Viscose. Manufacture of a new product from cellulose and caoutchouc. [Fr. Appl. March 28, 1908.]* March 26.

7433. Smith. Manufacture of indiarubber.* March 27.

COMPLETE SPECIFICATIONS ACCEPTED.

28,365 (1907). Immisch. Manufacture of ebonite and vulcanite. March 31.

3572 (1908). Wallace and Reynaud. Manufacture of elastic products similar to indiarubber. March 24.

27,328 (1908). Hayley (Northway). Obtaining indiarubber or caoutchouc. March 31.

28,159 (1908). Immisch. Manufacture of ebonite and vulcanite. March 31.

XIV.—TANNING, LEATHER, GLUE, SIZE, Etc.

APPLICATIONS.

6739. Stannard. Tanning and like processes. March 20.

7207. Glasel. Tanning drums. March 25.

COMPLETE SPECIFICATIONS ACCEPTED.

6142 (1908). Marter. Substitute for bone, ivory, etc. March 24.

15,009 (1908). Vidal. Treatment of hides and leathers, hair, furs, feathers, yarns, and threads. March 24.

XV.—MANURES, Etc.

COMPLETE SPECIFICATION ACCEPTED.

5999 (1908). Goeckeler. Method of treating manure. March 24.

XVI.—SUGAR, STARCH, GUM, Etc.

APPLICATION.

6917. Johnson. *See under XIII B.*

XVII.—BREWING, WINES, SPIRITS, Etc.

APPLICATIONS.

6397. Naeck. Maturing and purifying alcoholic liquors. [Fr. Appl. March 21, 1908.]* March 17.

7419. Sherman and Lutyens. Sterilising and cleaning brewers' casks, vats, and other vessels contaminated by putrefaction products. March 27.

COMPLETE SPECIFICATION ACCEPTED.

27,956 (1908). Breker. Production of brewers' wort. March 24.

XVIII.—FOODS; SANITATION, WATER PURIFICATION; AND DISINFECTANTS.

(A.)—FOODS.

APPLICATIONS.

6143. Little. Treatment of flour. March 15.

6178. Tildesley, Ritchie, and Watkins. Process for improving flour. March 15.

COMPLETE SPECIFICATION ACCEPTED.

6444 (1908). Frye. Process for making butter. March 31.

(B.)—SANITATION; WATER PURIFICATION.

APPLICATIONS.

6349. Thresh. Water purification. March 17.

6399. Thomson. Treatment of waste liquors. March 17.

6935. Payne and Staynes. Purification of water.* March 23.

COMPLETE SPECIFICATION ACCEPTED.

12,711 (1908). Pulsford. Water purifying apparatus. March 31.

XIX.—PAPER, PASTEBOARD, Etc.

APPLICATIONS.

6554. Schloss, and Fürst Guido Donnersmarck'sche Kunstseiden und Acetatwerke. Manufacture of solutions of cellulose acetate. March 18.

7206. Green. Manufacture or treatment of paper. March 25.

7302. Soc. Franç. de la Viscose. *See under XIII C.*

COMPLETE SPECIFICATION ACCEPTED.

5963 (1908). Pidelaserra y Brias. Manufacture of copying paper. March 24.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENTIAL OILS, AND EXTRACTS.

APPLICATIONS.

6114. Ransome. Compound for use in medicine and pharmacy. March 15.

6173. Fa weather (Valentiner und Schwarz). Producing a sulphur compound of quinine.* March 15.

6408. Boulit (Egyetemes Kísérlető Intézet Vegyészeti Orvosi). *See under I.*

7094. Justice (Boehringer). Manufacture of lactic acid.* March 24.

7315. Zimmermann (Chem. Fabr. auf Actien vorm. E. Schering). Catalysis for the hydrogenation or dehydrogenation of organic compounds. March 26.

7322. Kondakow. Manufacture of bornylene from dextro-pinene.* March 26.

COMPLETE SPECIFICATIONS ACCEPTED.

17,139 (1908). Meister, Lucius, und Brüning. Manufacture of acid derivatives of aminoarylsarsinic acids. March 31.

21,820 (1908). Ascoli. Yeast preparation suitable for hypodermic injection. March 31.

24,072 (1908). Hoffmann-La Roche und Co. Guaiacol compounds. March 24.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

APPLICATION.

7000. Triepel. Production of pigment prints, etc.* March 23.

COMPLETE SPECIFICATION ACCEPTED.

5641 (1908). Donisthorpe. Photographic sensitive surfaces. March 24.

The Society of Chemical Industry.

Past Presidents.

Sir Henry E. Roscoe, B.A., D.C.L., LL.D., Ph.D., F.R.S.	1881-1882.
† Sir Frederick A. Abel, Bart., K.C.B., G.C.V.O., D.C.L., D.Sc., F.R.S.	1882-1883.
† Walter Weldon, F.R.S.	1883-1884.
† Sir Wm. H. Perkin, LL.D., Ph.D., F.R.S.	1884-1885.
E. K. Muspratt, LL.D.	1885-1886.
David Howard	1886-1887.
Sir James Dewar, M.A., LL.D., F.R.S.	1887-1888.
Ludwig Mond, Ph.D., F.R.S.	1888-1889.
† Sir Lowthian Bell, Bart., F.R.S.	1889-1890.
† E. Rider Cook	1890-1891.
J. Emerson Reynolds, M.D., D.Sc., F.R.S.	1891-1892.
† Sir John Evans, K.C.B., D.C.L., LL.D., Sc.D., F.R.S.	1892-1893.
† E. C. C. Stanford	1893-1894.
T. E. Thorpe, C.B., LL.D., Sc.D., Ph.D., F.R.S.	1894-1895.
Thomas Tyrer	1895-1896.
† Edward Schunck, Ph.D., F.R.S.	1896-1897.
Frank Clowes, D.Sc.	1897-1898.
George Beilby, LL.D., F.R.S.	1898-1899.
C. F. Chandler, D.Sc., M.D., Ph.D., LL.D.	1899-1900.
Sir Jos. W. Swan, D.Sc., M.A., F.R.S.	1900-1901.
Ivan Levinstein	1901-1903.
Sir Wm. Ramsay, K.C.B., D.Sc., LL.D., F.R.S.	1903-1904.
Wm. H. Nichols, M.S., LL.D., D.Sc.	1904-1905.
Edward Divers, M.D., D.Sc., F.R.S.	1905-1906.
Eustace Carey	1906-1907.
Sir Boverton Redwood, D.Sc.	1907-1908.

† Deceased.

LIST OF COUNCIL, 1908-9.

President : *Raphael Meldola, F.R.S.*

Vice-Presidents :

Eustace Carey.	Walter F. Reid.
Dr. Edw. Divers, F.R.S.	A. Gordon Salaman.
Dr. J. T. Dunn.	Geo. C. Stone.
Prof. Percy F. Frankland, F.R.S.	Dr. T. B. Wagner.
A. R. Ling.	Chas. Wightman.
Sir Boverton Redwood.	R. C. Woodcock.

Ordinary Members of Council :

Prof. P. Phillips Bedson.	E. Grant Hooper.

Official Notice.

SOCIETY OF DYERS AND COLOURISTS.

The Council of the Society of Dyers and Colourists has presented to the Society a bronze replica of a design for a medal in memory of the late Sir William Perkin, by F. W. Pomeroy, R.A. The presentation was made on April 23rd by Prof. W. M. Gardner, on behalf of the Society of Dyers and Colourists, and acknowledged by Sir Boverton Redwood on behalf of the Society.

Canadian Section.

Meeting held at Toronto, on Thursday, February 25, 1909.

PROF. W. LASH MILLER IN THE CHAIR.

THE STASSFURT POTASH SALTS.

BY R. LESLIE EMSLIE.

Geology of the potash deposits in North Germany.—At the time of the formation of the immense Stassfurt salt beds, wherein lie cradled the valuable potash salts, the German Fatherland presented a different appearance from that of to-day. Then a great salt lake stretched itself over their land, being bounded on the west by a mighty mountain range, the remains of which we can recognise in the hills of the Rhine valley and the mountains of Great Britain. Also to the north this salt lake was hemmed in by another mountain range, the remains of which we find in the mountains of Scandinavia. To the east of the salt lake stretched a wide plain, of what we must suppose was desert land, for the plains of Russia have been little disturbed by volcanic upheavals. The prevailing climate at the time of the salt bed formations was varied. At first a decided desert climate prevailed, which practically prohibited all forms of vegetable life. Again we find climatic conditions which favoured the existence of *Dolicholum* shell fish. In the south the salt lake, which stretched over the whole of present-day Germany towards a mediterranean sea, became more or less completely cut off from that sea. It is probable that an island bar, extending from the neighbourhood of Geneva, over Basle, Munich, Regensburg, and Passau to near Vienna, formed this sea bar, and that the narrow, shallow channels located in the neighbourhoods of Geneva and Vienna, permitted the flow of the mediterranean sea into the salt lake.

Salt layers in process of formation are to-day only to be found in bodies of water having no outlet in desert rainless climates. In such the flow of water is directed towards the lowest levels, carrying thence the salts which it has dissolved out from the salt-bearing rocks on its course. When, under such circumstances, the evaporation exceeds the inflow of water, the salt solution becomes more and more concentrated until the salt is precipitated. On the grounds of these observations Prof. Johannes Walther, of Halle, expressed the opinion that the Permian salt beds are not the result of sedimentary deposits, caused by the cutting off by a bar of an internal sea, as most geologists held, but that they have been formed in a desert region.

Rock salt belongs to no particular geological formation; it may occur from Silurian times up to the present, wherever the necessary conditions for the formation of the same are fulfilled. The salt beds in North Germany, which are exceptional for their manifold forms of potassium and magnesium salts, belong either to the Permian, or they lie on the border of the Diassic and Triassic formations.

In North Germany the depth of the salt layers has been determined by deep boring. At Spereenberg, south of Berlin, boring was conducted to a depth of 1194 m. through the salt without reaching the bottom layer. In boring at Unseburg, near Stassfurt, the rock salt, underlying the potash bearing salts, was reached at a depth of only 80 m., the lower layer being reached at 1250 m. Under these salt layers anhydrite, black shale, and bituminous limestone were bored through and again, at a depth of 1280—1290 m., rock salt was struck; at 1295 m. boring ceased in grey anhydrite. The immensity of the rock salt deposit here may be realised from the fact that taken perpendicularly, the measurement is 990 m., the beds lying at an angle of 35° to 45°. Near Bernburg, the older rock salt only gave a measurement of 150 m. In this case bituminous limestone was reached at 592 m. and rock salt again at 630 m.

The deposition of the salt layers took place by the evaporation of the salt water. But since the usual quantity of sodium chloride (3—4 per cent.) present in sea water, would not nearly suffice to cause such a large precipitation, there must have been a constant influx of salt water during the period of evaporation. This influx of the salt solution must have been from salt bearing springs, or from the sea through a narrow channel, which had been so shallow that a backward flow of the concentrated solution was impossible. This theory of the formation of the salt deposits was brought forward as early as the middle of last century by Hugh Miller and Lyell, and was further elaborated by Oehsenius in his work, "Die Bildung der Steinsalzlager," in 1877.

The influx of salt solutions from salt-bearing springs could have occurred in various ways. The salt content might have been the result of the weathering of such eruptive rocks as lava, basalt, and granite, or the salt springs may have been caused by the dissolving out of salt-bearing mountain strata, which had originally become separated from sea water. This manner of formation may at the present day be observed where the Jordan flows into the Dead Sea, and in many locations in desert places. It is probable, however, that the immense salt deposits in North Germany were formed by the influx of sea water into the salt lakes, where the potash salts were laid down. At the same time considerable quantities of salt solutions from salt-bearing rocks may also have found their way there.

Considering the great variety of salts found in the potash mines, the study of the salt deposits may be looked upon as a science by itself, presenting an extensive field for investigation. The excellent and classical work of van't Hoff throws much light on the subject, showing the necessary degrees of concentration and temperature for the formation of the various minerals occurring in the potash layers, and the conditions under which they can exist. The investigations conducted by van't Hoff took into consideration the chemical and physical conditions necessary for the precipitation of the salts, but omitted the geological conditions. But since the geological occurrence of the potash salts presents the greatest general interest, in the following remarks geology will occupy the foreground.

Geological and mineralogical description of the anhydrite, polyhalite, and kieserite regions.—The salt layers near Stassfurt are interspersed at fairly regular intervals of from 8—9 cm. with a stratum of anhydrite averaging 7 mm. in thickness and known as "annual rings." If we take the depth of the beds at Unseburg (900 m.), then according to the number of anhydrite strata, taking them as annual rings, a period of some 10,000 years was necessary for the formation of the salt deposits there. It was formerly supposed that each year during the winter season or during a rainy season the deposition of the annual rings of anhydrite took place and that in the warm season, when the water evaporation would be considerable, the rock salt was deposited from the concentrated salt solution. This theory, however, seems to be incorrect; on the other hand, it is probable that the anhydrite was deposited during the warm period and the rock salt during the cold period, since for the precipitation of the anhydrite from a salt solution, a high temperature was necessary. Precht assumes that the sodium chloride

remained in solution during the warm period, and after the precipitation of anhydrite had ceased, the salt was deposited. If, for example, there was a difference of 15°C . temperature between the cold and warm periods—say the highest temperature was 70°C . and the lowest 55°C .—this would give a difference in the solubility of the sodium chloride of some 5 parts in 100 of water. In order to precipitate a salt layer of 9 cm. thickness it would have been necessary to lower the temperature of the salt water 15°C . with a depth of approximately 18 m. of water. Since next by evaporation the less soluble calcium sulphate and the sodium chloride would be precipitated, a concentration of the other lesser component parts of sea water, *i.e.*, salts of potassium and magnesium, would take place, and from these substances a rich mother lye would be formed, as we observe in salt pans, the great salt lakes, etc. If now the further influx of sodium chloride through sea channels be cut off, the mother lye will gradually become precipitated in various forms by the constant process of evaporation. The calcium sulphate yet present in sea water, next forms with potassium sulphate the "polyhalite strata," from which the second 60 m. thick zone of the salt deposits, the "polyhalite region," takes its name.

The border between the anhydrite and polyhalite regions is not very sharply defined. On the border the thin layers consist partly of anhydrite and partly polyhalite. In the middle layers of the polyhalite region the mineral has the following composition, $2\text{CaSO}_4 \cdot \text{MgSO}_4 \cdot \text{K}_2\text{SO}_4 \cdot 2\text{H}_2\text{O}$, and is recognised as an amorphous mass in the crystallised rock salt of which 92–93 per cent. is present in the polyhalite region. The limit of the polyhalite region is formed by the concentration of the magnesium chloride in the solution combining with the magnesium sulphate and being deposited as kieserite and the potassium as a double salt of potassium and magnesium chlorides (carnallite). In the mines in the vicinity of Stassfurt the polyhalite region is characteristically formed, but in the province of Hanover and in Thuringen it is much less extensive. Only a small part of the potash becomes deposited in the form of polyhalite, the greater part being found in the carnallite.

According to van't Hoff's investigations, at temperatures under 73°C . with increasing concentration of the salt sea, next carnallite and later kieserite become deposited. Potassium chloride could not, therefore, be formed with kieserite under 73°C . Above 73°C . we find other conditions, and it is possible that part of the potassium chloride may be deposited as sylvine with the kieserite. The calcium sulphate still present in the solution must again be precipitated as anhydrite since the limits of the polyhalite region are passed.

In corroboration of the van't Hoff investigation, Precht has recently determined that above the polyhalite region the rock salt is interspersed with strata consisting of anhydrite, carnallite, and kieserite, and that not until later, with increased concentration of the mother lye salts, does the pure kieserite become deposited. One must therefore separate the heretofore recognised kieserite region into a lower anhydrite-carnallite-kieserite region and an upper carnallite-kieserite region.

In former years there were differences of opinion regarding the formation of the kieserite. Bischoff expressed the opinion that magnesium sulphate was precipitated from the mother lye as a salt with 7 molecules of water ("bitter salts"), thereafter gradually losing water. He says: "After the whole of the salt layers had been deposited some force must have been at work which was capable of causing the gypsum and 'bitter salts' to lose their water of crystallisation, but which did not disturb the carnallite and tachydrate of the upper layers." On the other hand, Precht gave his opinion as follows: "The formation of the kieserite was dependent on the very hygroscopic properties of the magnesium chloride present in large quantity in the mother lye, which through its water absorbing action hindered the crystallisation of this salt, in its usual form, with 7 molecules of water of crystallisation." That Precht's theory was correct appears from the investigations of van't Hoff, who determined the degrees of temperature and concentration of the magnesium chloride solution

necessary for the precipitation of the magnesium sulphate as kieserite.

To become deposited simultaneously with kieserite the potassium chloride must be precipitated below 73°C . as carnallite and above 73°C . as sylvine. In order to determine the temperature at which the Stassfurt salt beds were formed, Precht recently investigated the occurrence of the kieserite and carnallite on the border of the polyhalite region, and thereby found in several layers a quantity of kieserite, carnallite, and anhydrite, and draws therefrom the conclusion that the formation took place at a temperature of from 70°C . to 80°C .

The transition from polyhalite to kieserite is not sharply defined. The kieserite and the first layers of carnallite appear directly over the polyhalite, likewise in thin seams, while the rock salt still predominates, but gradually the salt layers, with decreasing sodium chloride content, become richer in kieserite and carnallite. Since the formation of the kieserite is specially favoured by warmth it must be supposed that, as in the case of the precipitation of anhydrite and polyhalite, that the kieserite in the warm season and the carnallite in the cold season become crystallised out. The kieserite is present as a hard mineral, which draws water from the atmosphere and becomes converted into "bitter salt." In water it falls into a fine crystal powder while a partial solution takes place. The decomposition does not occur in a saturated solution of "bitter salt," since the latter prevents a partial solution of the kieserite. On the other hand, a saturated solution of sodium chloride acts on the kieserite in much the same manner as water. The whitish-grey kieserite is dense but transparent, possesses a spec. gravity of 2.517, and consists of 86.56 per cent. of magnesium sulphate with 13.04 per cent. water.

Carnallite and the overlying layers.—The carnallite region is a seam some 25 m. thick, extending over the whole salt deposits and is the particular layer in which the potash salts are mined. The average composition of the carnallite deposits is 55 per cent. carnallite ($\text{KCl} \cdot \text{Mg}(\text{Cl} \cdot 6\text{H}_2\text{O})$), 26 per cent. rock salt, 17 per cent. kieserite, and 2 per cent. of other substances (anhydrite, clay, boracite, etc.). Carnallite when absolutely pure is transparent and colourless; in salt mines it appears in its purest form as a whitish dense salt mass, whose plane of cleavage is not so uneven as that of rock salt. The cleavage surface is conchoidal and the specific gravity is 1.618. Carnallite is composed of 26.76 per cent. of potassium chloride, 34.5 per cent. of magnesium chloride, and 38.74 per cent. of water. In a moist atmosphere it is deliquescent, is easily soluble in water, and is only formed from solutions of potassium and magnesium chlorides which contain at least 25 per cent. of magnesium chloride. In nature pure carnallite is seldom found; it is, as a rule, streaked with rock salt. Even the purest piece which it is possible to find in the primary carnallite layers always contains sodium chloride, and likewise the secondary carnallite, which has recrystallised, is not free from rock salt. In the primary salt layers, carnallite is as a rule coloured; the colour varies greatly, sometimes being greyish from organic substances and clay, but in most cases red, due to peroxide of iron. The red colour is not observed in the carnallite which borders on the polyhalite region. Then it is free from iron, and only in the kieserite region does the iron content gradually appear, as in the original salt lakes the concentration of the solution become intensified. The peroxide of iron was not originally present as such, but, according to Precht's investigations, as a double salt of ferric chloride and out of which, through oxidation and decomposition of the crystallisation water of the carnallite hydrogen and peroxide of iron have been formed. Precht has named the iron chloride-potassium chloride "Donglasit." It is similar to carnallite in composition, and as a result of the simultaneous crystallisation of both double salts carnallite derived its iron content, while the rock salt and kieserite, occurring in fine layers between the carnallite, are free of iron.

The carnallite formation was interrupted by the deposition of a large salt-clay layer, some 8 m. in thickness, which was partly mechanically deposited from suspended slime, and partly by chemical means from the concen-

trated potassium chloride and magnesium chloride mother lye. In this way a cover was formed protecting the mother lye salts from being washed out by a subsequent inundation. The salt-clay, which in the western deposits occurs in three layers, contains, according to Precht's investigation, in the lower layer principally calcium sulphate, in the middle layer magnesia and aluminium hydroxide, and in the upper layer, besides clay, 40–50 per cent. of magnesium carbonate.

Overlying the salt-clay is anhydrite, formed by a renewed flooding of the basin, after the latter had been for a considerable period entirely cut off from the sea. The lower layers of the new red sandstone are formed by anhydrite, but partly occurring between both layers, is yet a younger rock salt layer, which was first discovered in New Stassfurt after the Stassfurt mines had been 15 years in operation.

The younger rock salt.—The younger rock salt differs from the older in its greater degree of purity; the former contains on the average 97.5 to 98.5 sodium chloride and the annual rings of polyhalite, which can hardly be perceived, are as much as 30 cm. apart. According to Precht the formation of the younger rock salt occurred in places where the older rock salt was not protected by an impervious layer; the latter became dissolved and again crystallised in the lying parts. This theory has been supported by more recent observations in the Hanover potash mines where the younger rock salt is present in immense masses, and here also the secondary potash salts are found. The formation of the younger rock salt is closely connected with that of the secondary potash salts, which will be referred to later. The younger rock salt is not found in all the mines in the neighbourhood of Stassfurt; it is lacking in the oldest Prussian mine, and also in Leopoldshall, while it is present in normal formation of some 80–120 m. in thickness in the Achenbach, New Stassfurt, and the Ludwig II. mines. In the vicinity of Stassfurt potash salts are not found in the younger rock salt layers, but in the province of Hanover, particularly in Salzedetfurth, where the beds are 200–300 m. thick, sylvinites and carnallites of remarkable purity are present. In the salt mines of North Germany rock salt is mined in large quantity, all being taken from the younger rock salt layers. The older rock salt is not mined any more for that purpose, but is used for filling in old workings in the potash mines.

The present profile of the potash beds.—All the salts were originally deposited in horizontal layers or with only slight deflection from the horizontal, due to unevenness of the sea bottom. In this position they are seldom found at the present day, being unusually inclined at a considerable angle. The breaking of the earth's surface through volcanic upheavals and the contraction of the earth's crust have thrown them into every conceivable position. In the neighbourhood of Stassfurt in the upper workings of the mines, in consequence of the upheaval of the Stassfurt-Egeln oolitic saddle, the potash salts are found at an angle of from 45°–70°, while in the lower levels they lie almost horizontally. To the east and south of Stassfurt, at Bernburg and Aschersleben, they are found very little inclined, whereas to the north of Stassfurt at Westeregeln, the degree of inclination is usually very high. In the province of Hanover, the salt beds have been generally very much disturbed. At Vienenburg they are almost perpendicular, and in the profile of Justice von Volprichausen, between the Leine and the Weser, one may recognise the action of mountain pressure in the lower levels of the salt mine. Interesting experiments by Rinne have shown how rock salt and sylvine in a plastic state may be remodelled by the application of pressure, similar to observations frequently made in salt mines. The profile of the salt layers of Jessenitz in Mecklenburg, show serpentine lines running up and down which were doubtless formed by lateral pressure of mountain masses. One recognises in these profiles widely varying conditions, but one cannot draw the conclusion that all the salt beds in Hanover and Braunschweig were subjected to the same crushing force, for in individual mines the layers are often regular. The potash salts in the salt basins between the Harz and the

Thüringer forest and the south-west of the latter, on the Werra, show generally regular layers, but through the influx of water and the consequent formation of secondary salts, they are much changed.

The potash salts of secondary formation: Sylvinites, hartsalz, and kainite.—The oceanic potash deposit of primary formation, the carnallite, is almost exclusively used in the potash factories in the preparation of potassium chloride and other potash containing products and is employed only to a small extent in its raw ground state in agriculture. But the aforementioned potash salts of secondary formation, which have been produced from the primary deposits through the action of water, are for the most part ground and used directly as potash fertilisers.

Sylvinites is a mixture of pure sylvine (potassium chloride) and sodium chloride; it is mostly free from magnesium sulphate, or contains only negligible quantities thereof. The potassium chloride content of the sylvinites fluctuates between 20 and 60 per cent.; in several places it has even been found as high as 90 per cent., but such an occurrence is rare, and the quantity small. The sylvinites is white in appearance and scarcely to be distinguished from rock salt. In hardness it is the same as rock salt, but the specific gravity is less dependent on the amount of potassium chloride, since pure potassium chloride has a sp. gr. of 2.0 and sodium chloride a sp. gr. of 2.2. In most cases sylvine contains, besides the rock salt, also kieserite, and is then named "Hartsalz" on account of the great hardness of the kieserite. Its composition is approximately 20–22 per cent. sylvine, 10–15 per cent. kieserite, and some 60 per cent. rock salt.

Kainite in a chemically pure condition is a white, finely crystallised mineral, but seldom occurs as such, being as a rule, mixed with about 30 per cent. rock salt; the other substances are insignificant, so that the commercial article is usually a mixture of kainite and rock salt. Pure kainite may be considered as a crystallisation of potassium sulphate, magnesium sulphate, and magnesium chloride, with a formula, $K_2SO_4 \cdot MgSO_4 \cdot MgCl_2 \cdot 6H_2O$. It may also be considered a crystallisation of potassium chloride with magnesium sulphate, having the formula, $KCl \cdot MgSO_4 \cdot 3H_2O$. In commerce the first formula is generally used, and according to it the composition of kainite is, 24 per cent. potassium sulphate, 16.5 per cent. magnesium sulphate, 13 per cent. magnesium chloride, 14 per cent. water, 31 per cent. sodium chloride, and 1.5 anhydrite and clay. Kainite in crystals is also found as a mineralogical curiosity.

The secondary salts are recognised as products of the metamorphosis of the primary carnallite layers. This metamorphosis has taken place in various ways, and Precht distinguishes between the formation of secondary salts on the original and on extraneous beds. The first manner of the formation on the original beds followed in this wise: Water acted on the carnallite layers, dissolved the magnesium chloride and left the less soluble salts behind, the latter being rock salt, kieserite, and the potassium chloride which had been dissolved out of the carnallite. This "Hartsalz" had been formed at a temperature above 73° C., so that kainite at that geological period was not capable of existing. The formation of the kainite followed much later, likewise on the original beds, but according to investigations of van't Hoff at a temperature below 73° C. In the formation of kainite as in that of "Hartsalz" the magnesium chloride must have been dissolved out from the carnallite and at the same time a magnesium or calcium sulphate solution must have been introduced in order, through the interchange with potassium chloride, to produce this mineralogically interesting mineral.

The secondary formation on extraneous beds followed through the solution and recrystallisation of the older primary salt layers, in the same way as with the younger rock salt, and, since besides rock salt carnallite could also be dissolved, it stands to reason that in the younger rock salt layers, potash salts would also be formed on secondary beds. One can represent this process in many ways.

Suppose a salt layer, composed of rock salt, carnallite, and kieserite, were dissolved, kieserite as the least soluble ingredient would remain behind, and from the concentrated brine solution, which has flowed to the lower lying points, the rock salt would next crystallise out, then sylvinit, and lastly white secondary carnallite. If through atmospheric precipitation, the carnallite salt at the higher lying points became quite dissolved, and again crystallised out in lower situation, then with renewed water action rock salt solutions could form, which, likewise, would flow to lower levels and there crystallise out. It is therefore possible to explain the occurrence of secondary carnallite, re-covered by a rock salt layer. But this sodium chloride solution could again decompose the already deposited secondary white carnallite and convert it into sylvinit, and in this way it is not difficult to find an explanation of the sylvinit layers overlying those of carnallite. Regarding the geological age of the secondary formation, Precht divides the time into three periods: The first period of the carnallite decomposition commenced soon after the carnallite formation, partly before and partly after the laying down of the salt-clay, as soon as the salt layers were accessible to the influence of water or dilute salt solution. During this period, Hartsalz layers were formed almost free from iron, since the formation occurred at a time when the ferric chloride, contained in the carnallite, had not yet become oxidised. The ferric chloride was washed out with the magnesium chloride and, therefore, in Precht's opinion the peroxide of iron content of Hartsalz depends on the period of its formation. The secondary potash salts of the oldest period of formation became covered by the later deposited salt-clay and anhydrite, and then the second period of the secondary formation commenced in which, before the formation of the new red sandstone, the younger rock salt was formed by the solution and recrystallisation of the older salt layers. With the younger rock salt the secondary potash salts, sylvinit, and white carnallite, also formed on extraneous beds. One must imagine in this period of formation, North Germany as a great salt desert, where through solution or recrystallisation of the salt beds the multitudinous changes took place the evidence of which we find at the present day in the potash mines. As the third period, Precht marks the later secondary formations, which occurred after the new red sandstone was laid down. The chief product of this period is the kainit, and therefore it may be designated the kainit formation period. The formation of kainit resulted from the access of water to the carnallite layers, through cracks in the earth, dissolving magnesium chloride and effecting the aforementioned changes. This period reaches far back into the more recent geological ages, perhaps as far back as the tertiary formation, as the temperature of the earth's surface was even then so reduced that the formation of kainit was possible. The geological occurrence of kainit indicates that it was never of primary formation, but always a secondary product. These observations support Precht's theory that the primary salt beds were formed at temperatures over 73° C.

The Hartsalz of the first period on the original beds is widely distributed. It occurs extensively in the lower levels of the oldest mines in the neighbourhood of Stassfurt, also in Aschersleben and in the Deutschen Solyay mines. It is also found in large quantity between the Harz and the Thüringer Forest, and particularly in the potash mines on the Werra, where the Hartsalz is largely found as the carnallite salt. In the province of Hanover the mines are provided with large layers of either Hartsalz or carnallite: Justus and Hohenfels have only Hartsalz, while in most of the others in Hanover Hartsalz and carnallite are both encountered. The secondary formations of the second period, on extraneous beds, occur less seldom. Sylvinit is found most extensively and also in purest condition in Viernburg and Salzdetfurth. Also in the mines south of the Harz Mountains the secondary potash layers are recognised as sylvinit, although not altogether free from magnesium sulphate. The kainit of the third period occurs in largest quantity in the Magdeburg-Halberstädt salt basins, while it is seldom found in the province of Hanover and has never been discovered in the mines south of the Harz and on the Werra. Kainit

has usually a fine crystalline structure and is easily distinguished from carnallite, but kainit is sometimes found in coarse crystals and is then difficult to distinguish from the former. For instance, in Braunschweig there is kainit, which in outward appearance closely resembles carnallite. In order to determine the presence of kainit, especially in a mixture of kainit and carnallite, Precht's method of analysis will serve: this is founded on the solubility of the magnesium chloride of the carnallite in absolute alcohol, while all non-carnallite salts of commerce, kainit included, contain no magnesium chloride soluble in alcohol. By titration of the alcohol-soluble chlorine, this method of analysis, which is prescribed by the Kalisendikat, is easily and quickly carried out. The carnallite occurs in all North Germany salt in large quantities, as the secondary salt of all three formation periods.

Of the great number of minerals which are encountered in the potash mines, there are yet a few also of secondary formation worthy of mention.

Schönit ($K_2SO_4 \cdot MgSO_4 \cdot 6H_2O$) presents itself in the various mines of the Magdeburg-Halberstädt salt basins on the kainit beds and is mixed along with the kainit. Likewise *Krugit* ($K_2SO_4 \cdot MgSO_4 \cdot 4CaSO_4 \cdot 2H_2O$), which was discovered by Precht in the younger rock salt layers, is mined in small quantities. Of those most recently discovered minerals *Langbeinit* ($K_2SO_4 \cdot 2MgSO_4$) is most frequently met with. It was found by Zuckschwerdt, in 1891, in the bore hole at Wilhelmshall, after Precht in 1881 had demonstrated the formation of this insoluble double salt of potassium and magnesium sulphates at the factory. Langbeinit is usually found in a Hartsalz layer, particularly under the Hartsalz, where in primary deposits the kieserite is met with. It is usually so streaked with rock salt that its mining is unprofitable and only in individual places is it worth mining.

The following secondary minerals have only a scientific interest:—*Astrakanit* (Bloedit), $Na_2SO_4 \cdot MgSO_4 \cdot 4H_2O$; *Bischofit*, $MgCl_2 \cdot 6H_2O$; *Glaserit*, K_2SO_4 ; *Glauberit*, $CaSO_4 \cdot Na_2SO_4$; *Loewit*, $Na_2SO_4 \cdot MgSO_4 \cdot 2H_2O$; *Reichardt*, $MgSO_4 \cdot 7H_2O$; *Tachhydrit*, $CaCl_2 \cdot 2MgCl_2 \cdot 12H_2O$; *Vanthoffit*, $3Na_2SO_4 \cdot MgSO_4$.

Stassfurt a salt market in mediæval times.—Stassfurt, the centre of the potash industry, has been noted for its saline springs from very early times, and in the year 800 A.D. was, we are told, the site of an important salt market. According to tradition, the saline springs were discovered by a leader of the Wends in North Germany, who was taken prisoner by Charlemagne. At first the ownership of the springs was divided amongst the burghers of the town, there being then about 30, but in the 15th century the salt springs were already in the hands of a company the members of which formed part of the Stassfurt Municipal Council. The industry was of very great importance to the locality and formed the chief means of livelihood of the inhabitants. After the commencement of the 18th century, through lack of improved methods of production, the industry gradually fell off, and eventually in 1797 the company sold their rights to the Prussian Government for the sum of 85,000 Taler. With the introduction of new improvements, including boring, the salt mining industry was carried on by the Government into the sixties of last century. In 1851 the first two shafts were sunk with the object of mining the rock salt, and in 1857 the output of salt in this form commenced. At first only the rock salt was used, but the overlying layers of impure "Abraumsalze," whose presence created surprise, soon aroused the interests of scientists. When it was discovered that the "Abraumsalze," or waste salts, which were encountered in mining the rock salt, contained potash, the attention of scientists was turned to these potash bearing salt layers, and very soon factories were established to manufacture potassium chloride. The "Abraumsalze" which had accumulated in large heaps near the pit heads, were soon used up.

Liebig's discovery of the value of potash salts in agriculture was made in the early sixties, and from that period the output has steadily increased until it has reached its present immense proportions, but by no means its limit.

The following figures show the increased consumption of the more important potash salts for agricultural purposes since 1903 :—

	1903.	1907.
	Tons.	Tons.
Potassium chloride—		
Total output	206,347	291,248
North America	71,279	111,852
Potassium sulphate—		
Total output	38,407	56,253
North America	19,747	28,453
Potassium-magnesium sulphate—		
Total output	22,296	31,503
North America	11,944*	15,545
Potash manure salt—		
Total output	153,415	255,810
North America	59,655	60,252
Kainit and sylvinit—		
Total output	1,466,839	2,207,226
North America	243,704	379,449
Germany	979,986	1,456,824

* 1906.—20,666 tons.

Mining and refining the salts.

Mining.—The sinking of the first shafts named "von der Heydt and von Mantenfel" by the Prussian Fiskus near the Bode River at Stassfurt was carried out with little difficulty. They were not built up with stone but remained wood-lined and had notwithstanding only a small water influx. Likewise the two first shafts of the Ducal-Anhalt salt mine at Leopoldshall were put down without difficulty and this is very fortunate for the potash industry, for if in the sinking of the first shafts the same difficulties had been encountered, as have since been met with, the mining of potash salts would have commenced much later. In many of the more recently opened shafts the inflow of water was so great that the sinking could not be conducted in the usual way, by manual labour, and recourse was had to other methods. The cost of shaft sinking varies very greatly and many companies have sunk large sums of money. Shafts with wood lining are now scarcely to be found. Should the water inflow not be strong the shaft is lined with stone or brick cement work, but where the inflow is great and the shaft deep iron tubing is used in order to prevent the inflow as much as possible. All the older potash mines have several shafts, which in most cases are connected underground, but are often separated by safety guard walls in order to protect in reserve some of the workings should water break in. All the younger mines possess only one shaft. The depth of the shaft at present varies from 300 to 800 m., one in New Stassfurt being that depth; almost one half mile.

The mining of the potash salts in the Royal-Prussian and Ducal-Anhalt mines during the period between 1860 and 1886 was conducted on several levels, which extended in both directions along the horizontal for several kilometers. The workings were at right angles to the former with a breadth of 9 m., while the height of the same varied according to the distance apart of the levels (from 8 to 14 m.). Between the workings, a column of 6 m. thickness remained standing, and between the levels a ceiling of from 6 to 8 m. strength, which served as a support for the overlying layers. The length of the workings was regulated by the angle of the potash layers. Although in this way only 40 per cent. of the carnallite was mined and 60 per cent. remained, still this method did not prove sufficiently durable, since in Leopoldshall and Stassfurt the slanting levels collapsed. These subsidations in the mines have made themselves noticeable by depressions on the surface and have led to very heavy damages being collected from mine owners. The inflow of water is partly caused by the collapse of the columns and ceilings in the pure carnallite workings, carnallite not being a very compact substance, and the subsequent depression of the surface, which aids the access of water to the mine; it may also be caused by pushing the workings too far in the upper levels and coming too near the water bearing earth strata. These unfortunate experiences led both the fiscal mines to make extensive

alterations in their mining methods, especially to enforce the systematic filling in of the old workings with rock salt from the layers of the older rock salt or with residue from the factories, ashes, etc. The old rock salt is specially mined for this purpose. It is not considered necessary to fill in the excavations (Bergmühlen) made in mining the old rock salt, the latter being a more stable substance than the carnallite. By this precaution the loss of workings, by the falling in of the ceilings between the levels, was considerably lessened. The principal tramways were also laid along the lower levels in the kieserite region (consisting chiefly of rock salt and kieserite), instead of along the upper level as formerly. In the mining of the salts explosives are always employed. Boring is performed either by hand, compressed air, or electric drills, the latter being operated by means of a transportable motor, protected in a box with flexible shafting. A slow working powder is used in blasting the potash salts, containing chiefly sodium nitrate with about 15–20 per cent. of potassium nitrate. In the hard firm salt beds a quick-acting powder has been used with good effect. In the Hartsalz layers the bore is filled three-quarters with ordinary gunpowder and lastly with a dynamite cartridge. With the discharge of the dynamite the mass is loosened, so that on the subsequent ignition of the gunpowder a larger amount of material is dislodged.

Carnallite, kainit, and Hartsalz are partly separated from worthless salts—kieserite and rock salt—by hand picking in the mine, so far as this is possible. They are then removed in the small tram waggons, the individual capacity of which is from 1200 to 1600 lb. The hauling is partly done by manual labour, partly by endless rope, or by overhead electric wire haulage. In recent time electric haulage has become very general for the long distance tramways. The salts are usually ground at the pit head, in which process stone crushers and so-called "coffee mills" besides fine powder mills are employed. The first mills deliver a coarse product which is afterwards reduced to the required fineness by means of mill stones, etc.

Manipulation of the crude potash salts in the factory in the preparation of potassium chloride and sulphate, "potash manure salt," and kieserite blocks.

Experiments in the preparation of potassium chloride from carnallite were made in several chemical factories in Germany in 1860 and 1861, but those more remote from Stassfurt soon gave up the manufacture, since on account of high freight charges they could not compete with other factories, meantime opened at Stassfurt. In Stassfurt the first potassium chloride factory was founded by Frank in the year 1861. The number of the factories quickly increased on account of the high price obtained for the product, and in 1864 they were already twelve in number, which, however, led to overproduction, and had the effect of greatly reducing the price. After the recovery from this first crisis, the manipulation of the salts kept pace with the output, and soon many more factories were established in Stassfurt, Leopoldshall, and the surrounding neighbourhood. The production of potassium chloride depends on the crystallisation of this salt from a hot saturated carnallite solution, during cooling, whereby magnesium chloride remains in solution. Although this crystallisation process appears very simple, yet little by little, after much experience, important improvements have been introduced. The manufacture may be divided into the following operations:—1. Dissolving the crude salt. 2. Steaming the mother lye. 3. Dissolving the artificial carnallite. 4. Purifying the crystallised chloride. After the crude salt has been ground it is placed in elevated, solvent bottles of about 12 cubic meters capacity, containing a boiling solution of magnesium chloride. By simultaneous admission of steam, potassium chloride and magnesium chloride are dissolved, while the rock salt and kieserite remain undissolved. The resultant hot solution is then allowed to clarify from the suspended ingredients (kieserite and clay slime) in special receptacles, thereafter being admitted to iron crystallisation vats, in which on cooling, after 3 or 4 days, a mixture of potassium chloride and common salt crystallises out. The mother lye may not contain

more than 21 per cent. of magnesium chloride, since with a higher concentration, after the crystallisation of the potassium chloride, artificial carnallite would also be deposited, whereby the purification of the potassium chloride, by covering with water, would be rendered more difficult. In order to reclaim the potassium chloride in the mother lye the latter is steamed in vacuum to that degree of concentration, when carnallite in the form of artificial carnallite crystallises out, only 5 per cent. remaining in the solution. The artificial carnallite is dissolved in hot water or lye and on the solution cooling, a second crystallisation of potassium chloride is obtained. The potassium chloride from both crystallisations is purified from magnesium chloride and partly from sodium chloride by washing with water at the ordinary temperature. It is then steam heated in the calcinating ovens, passed through rotating cylinders and other drying apparatus, whereby it is made ready for export. It then contains 50 per cent. of actual potash. The remaining lye and washing waters are employed in dissolving the crude salts or the artificial carnallite. Of the potassium chloride present in the crude salts, 85 to 92 per cent. is extracted while the rest is lost in the residual solution and sediment. The sediment, according to the quality of the crude salts employed, may be very rich in potash, so that it sometimes pays to calcine this residue and use it in the preparation of "potash manure salts."

Potassium sulphate is now chiefly prepared by the action of magnesium sulphate on potassium chloride in a dilute solution. Its formation does not take place quantitatively but is dependent on the quantity and the conditions of the two salts, and on the concentration of the solution. The reaction, in presence of magnesium chloride, formed therewith, may even go in the opposite direction, and therefore, as a rule, potassium-magnesium sulphate is first formed, since with the formation of a double salt the backward action is less to be feared. The preparation of potassium sulphate then follows from the potassium-magnesium sulphate, under the action of potassium chloride in excess.

The factory process is as follows:—The estimated quantity of double sulphate is dissolved in hot water and stirred in a tossing tub with an excess of potassium chloride, the potassium sulphate forming as a fine crystalline pulp. To prevent the precipitation of potassium chloride the temperature must not fall below 50° C. The deposited potassium sulphate is then separated from the mother lye by tip-buckets, covered with water and calcined. It is put on the market with 90 to 95 per cent. of potassium sulphate and not exceeding 2½ per cent. of chlorine, or with 96 per cent. of potassium sulphate and not exceeding 1 per cent. of chlorine, the former being used for industrial purposes and the latter finding an extensive application in agriculture.

Glauber salt, bromine, and magnesium chloride.

The manufacture of Glauber salt, which is confined to the winter season, is based on the reaction which takes place at temperatures below freezing point, in a dilute solution containing sodium chloride and magnesium sulphate. The residue from the manufacture of potassium chloride is dissolved in hot water and the resulting concentrated lye, after clarifying, is exposed to the winter cold in elevated shallow wooden cooling tanks. With moderate cold the crystallisation is accomplished in one night. The Glauber salt produced in this way is very pure, being free of iron, and therefore especially suited for the preparation of white glass.

The large quantities of final lye from the manufacture of potassium chloride partly serve for the production of bromine and are then run into the rivers, or they may be used in the manufacture of magnesium chloride. The bromine distillation takes place from the heated lye by means of manganese dioxide and sulphuric acid in granite or sandstone vessels, or by the introduction of gaseous chlorine. Now electrolytic methods are also employed in bromine production, but liquid chlorine is mostly used on account of its present low price.

Magnesium chloride is produced by steaming the final lye, whereby the iron present is deposited, and then running the clarified, somewhat cooled solution into

iron or wooden vessels. It is employed in the textile industry, but also in the preparation of flooring. For this purpose it is worked into a mass with water, burned magnesia, and a filler, is stroked over in the same way as ordinary cement and quickly hardens.

Industrial application of the potash salts.

The preparation of *caustic potash* and *potashes* employs about one half of the potassium chloride used in industry. Both are chiefly employed in soap manufacture. Potashes are also employed in glass and paper manufacture, in the preparation of colours, in printing and photography.

The next important product is *salt-peter*, in the manufacture of which one-third of the total industrial potassium chloride is used.

The three products, caustic potash, potashes, and salt-peter, used up five-sixths of the industrially employed potassium chloride. The remaining sixth part is divided amongst a few other products, of which the more important is *potassium chlorate*, claiming one-eighth of the total potassium chloride. Its chief use is in the preparation of matches, and since there is a growing tendency to produce matches free of sulphur and phosphorus, its use is on the increase. For example, in 1889 8000 tons were prepared for this purpose, and in 1903, 14,000 tons.

In the manufacture of *potassium chromate* one-twentieth of the industrial potassium chloride is employed. This is used in the textile and colour industries and in modern photographic printing and reproduction processes.

In 1880, rather more than half the total production potash salts was still used for industrial purposes; in 1885 the agricultural was equal to the industrial consumption. In 1888 53 per cent. of the potash salts was used in agriculture, in 1905 84·3 per cent., until at the present day industries use less than 15 per cent. of the total production of potash.

London Section.

Meeting held at Burlington House on Monday, April 5th, 1909.

MR. E. GRANT HOOPER IN THE CHAIR.

BOGHEAD CANNEL OR "TORBANE HILL MINERAL," AND OTHER SO-CALLED "BITUMINOUS COALS."

BY WATSON SMITH.

(ABSTRACT.)

After exhibiting a fine specimen of this now extinct coal given him by the late Dr. Jas. Young, F.R.S., and after a brief historic and chemical description, the author pointed out that whereas in the celebrated trial of 1853, it was decided that the mineral in question was a coal, immediately afterwards, a similar trial conducted in Berlin under the auspices of the Zollvereindirection yielded just the contrary result, so that whereas in Britain the substance was "coal," in Germany it was regarded as "a bituminous substance, but not coal." He then drew attention to the fact that not only is "coal" a term involving some ambiguity, as being strictly a commercial or trade term, but so likewise, even to a greater extent, is the word "bituminous" as applied to coal, the amounts of actual bituminous matter soluble in benzene and similar solvents in the richest cannel, being mostly below 1 per cent. and too small to appreciably affect the physical properties of the mineral. Among all the known coals, a great exception is the Japanese Miike coal (a lignite), with 9·5 per cent. of bitumen (this J.L. 1892, 591; also 1891, 976). In this case the physical properties are affected by the presence of so much bitumen, for the coal yields volumes of intensely black smoke when it is used for firing up. The term "bituminous" has doubtless been chiefly applied in the past to cannel and caking coals, etc., because of the external pitchy or bitumen-like appearance they have been thought to present, and because in burning, certain of them undergo a kind of semi-fusion, with decomposition. To remove a dangerous

ambiguity which might, in contracts, etc., give rise to disputes, the author proposed the entire abolition of the term "bituminous" as applied to coals.

DISCUSSION.

Mr. O. GUTTMANN said that this mineral played at one time a certain part in connection with the manufacture of explosives. The early dynamite was absorbed by kieselguhr, and between 1865 and 1870, it was thought that silica played an important part in the constitution of dynamite. During the siege of Paris, when it was required to produce dynamite, the necessary silicious material was obtained in the ashes of Boghead coal.

VAPOUR-GALVANISING.

BY S. COWPER-COLES.

Vapour-galvanising is distinctive from all other forms of galvanising inasmuch as the vapour of zinc is employed for coating metal surfaces instead of dipping them into molten zinc or into an aqueous solution through which a current of electricity is passed.

Vapour-galvanising can be subdivided under two heads, namely, the zinc dust process and the molten zinc vapour process.

Zinc dust, which is an essential feature of the first process, is the product formed during the distillation of zinc from its ores, but, as the demand now exceeds the supply obtainable, by the ordinary process of distillation from the ore, it is made by distilling zinc from the crude metal. Zinc dust usually contains about 80 per cent. of metallic zinc, coated with a film of oxide, which prevents the metallic zinc from running into a molten mass when heat alone is applied. It is therefore

FIG. 1.—Furnace for vapour-galvanising.

particularly suitable for the process about to be described, as all risk of fusing and coating the iron under treatment with molten zinc is thus obviated. Zinc dust volatilises at a low temperature, due no doubt to its unstable physical condition. This fact was observed when some experiments were being made in connection with the annealing of cast iron in 1902. Zinc dust, when in contact with another metal, such as iron or copper, volatilises at a much lower temperature than it would otherwise; a piece of iron placed in zinc dust and heated to a temperature several hundred degrees below its melting point is quickly coated with zinc; if a similar piece of iron is suspended just above the zinc dust, no deposit of zinc takes place. In the former case an electric current is generated which probably reduces the volatilising point.

The process of vapour-galvanising with zinc dust in practice is carried into effect in the following manner:—The zinc dust and the iron articles to be coated are placed in an air-tight iron drum, which is heated in a gas-fired furnace, as shown in Fig. 1, to obtain a temperature within the drum of about 600° F., that is to say, the zinc dust is brought to about this temperature. The length of time at which the drum is kept at this temperature depends

FIG. 2.—Method of discharging contents of drum.

on the thickness of the coat required, a few hours usually sufficing. The drums are emptied over an iron grid, Fig. 2, which retains the zinc-coated articles and allows the zinc dust to fall into a receptacle from which it is carried by a bucket elevator to a bin ready for recharging the drums. The iron articles, when cleaned from the zinc dust by means of a steam jet, are found to be coated with an even distribution of zinc which is alloyed with the iron surface, as shown in Fig. 3, the depth of the alloy depending both on the temperature and the length of time the minimum working temperature is maintained. The zinc iron alloy is non-corrosive, and does not rust even when the zinc surface has been removed by abrasion.

A complete apparatus for coating small articles such as bolts, nuts, and screws, is shown in Fig. 4, and consists of an iron drum, heated by gas and rotated by hand, or by suitable gearing. It is found in practice that the iron drum does not become coated with zinc even after being in use for several years, due to the high temperature of the drum as compared with the temperature of the zinc dust. When it is desired to obtain a thin even distribution of zinc, as for instance on thin steel plates, which are being used in place of lithographic stones, it is advantageous to mix the dust with some inert material such as finely-divided silica, excellent results being obtained with 9 parts of silica to one of zinc dust. The amount of zinc oxide present can vary considerably and yet give good results, the percentage can readily be controlled by adding hydrocarbon, by greasing some of the articles to be zinc-

FIG. 4.—Gas-heated furnace for small articles.

coated, or by adding finely-divided carbon to the zinc dust.

It was at one time thought that zinc dust containing carbon might have a detrimental effect on the nature of the deposit, due to the retention of small portions of carbon setting up galvanic action in the presence of moisture; the microscope did not reveal any particles of carbon on the zinc surface. The carbon required for reducing any excess of oxide is more efficacious if added in the form of a hydrocarbon instead of in the form of finely-divided carbon.

The advantages of vapour-galvanising are that it is cheaper than the ordinary hot-galvanising, forms a better protection and at the same time enables screw threads and machine work to be coated with an even distribution of zinc, so that the parts fit together and work quite freely, proper allowance having been made for the required thickness of the zinc.

In vapour-galvanising sheets, they are placed in a drum rotating in a furnace; each time the drum is rotated the sheets, which are held between knife edges, take up a different position, thus ensuring the plates being free from flaws and weak places in the zinc coating.

The surfaces obtained by hot-, electro-, and vapour-galvanising are different in each case, so much so they can be readily distinguished by anyone conversant with the three processes. In the case of hot galvanising, the surface is spangled, or, if not spangled, has the appearance of cast metal. In the case of electro-galvanising, the surface is free from spangles, but has a matted or frosted surface, which is uniform if the work has been well executed. Vapour-galvanising is again distinctive from the two former processes, the general appearance resembles more that of electro-galvanising than hot-galvanising, but is more lustrous and metallic and the coating is more uniformly distributed over the whole surface than in the case of hot and electro-galvanising processes.

The copper sulphate tests, known as Preece's test, namely, one minute's immersion in a saturated solution of copper sulphate, is not applicable as a comparative test of the thickness of zinc applied by the vapour or electro-zincing processes, for the following reasons:—On applying Preece's test to vapour-galvanised articles and hot-galvanised articles coated with an equal thickness of zinc, the former require from three to four times the number of immersions which suffices to remove the zinc from the latter. When hot-galvanised articles are placed in a saturated solution of copper sulphate, the copper is precipitated in a loose form, but when vapour-galvanised or electro-zinc-dipped articles are similarly treated the copper adheres firmly to the zinc and no fresh surface is exposed, apparently due to the deposit of zinc applied by the electro-zincing and vapour-galvanising processes having a fine matted surface.

It would appear from these observations that the apparently great resistance to corrosion of vapour-

galvanised iron when subjected to Preece's test is due to the protection of the zinc by the deposited copper, therefore, experiments were made with a solution of ferric sulphate, which dissolves zinc without forming a precipitate on the zinc coating. To test this, known areas of vapour-galvanised and hot-galvanised plate were exposed to the action of ferric sulphate solution for an equal period and the amount of ferrous salt formed by the reducing action of the zinc determined. The column headed "Weight of zinc dissolved" shows the relative corrosions:—

No.	Sample.	Zinc, per sq. ft.	Weight of zinc dissolved.
		grms.	grms.
1.	Vapourised (zinc dust process)	26.908	0.080
2.	" " " "	26.908	0.074
3.	" " " "	22.93	0.057
4.	Hot galvanising	22.12	0.058
5.	Vapourised (zinc dust process)	31.116	0.03

Sample No. 2 was moistened with water and allowed to dry, the oxide formed appeared to protect the zinc, and this protection is more marked if water is allowed to act for a longer period than was done in these experiments. The variations in the results are probably due to the amount of zinc iron alloy formed, dependent on the temperature employed. Sample No. 5, vapourised copper, although the zinc coating was the heaviest, yet the corrosion was in this case the least, due no doubt to the amount of brass coating formed beneath the comparatively thin zinc coating. On testing this sample, as in the other cases, with copper sulphate solution, instead of a brown precipitate of copper, a bright metallic deposit was obtained and no further action seemed to occur. From the results of these experiments and other tests, it may be concluded that vapourising offers equal and probably greater resistance to ordinary corrosive influence than hot-galvanised iron coated with an equal weight of zinc, and the resistance is considerably increased by repeated moistening and drying, so as to form an oxide which renders the surface less soluble.

FIG. 5.—Apparatus for vapour-galvanising with metallic zinc.

The second process referred to at the beginning of the paper, namely, the molten zinc vapour process, does not necessitate the use of zinc dust, nor are the materials to be coated brought into contact with the molten metal or any of its compounds; they are placed in a separate chamber filled with zinc vapour or placed above the molten zinc. A convenient form of apparatus is shown in Fig. 5. It consists of an inner drum, C, composed of wire netting or gauze, in which the articles to be galvanised are placed. This cage or hollow drum is slowly rotated inside an outer cylinder, B, composed of wrought iron, in which the metallic zinc is heated by means of gas or an electric furnace or any other suitable means, to a temperature

sufficiently high to volatilise the zinc. Hydrogen or other suitable gas is forced into the apparatus through the tube, A, and a pilot of hydrogen is kept burning through a small hole in the door, D, which makes a gas-tight joint when closed. The apparatus for vapourising has to be modified to suit various requirements, but, in almost all cases it is necessary to move the objects to ensure their being evenly coated with zinc.

A modification of the vapour process is applied to the inlaying and decorating of metallic surfaces. The *modus operandi* briefly consists in coating the article to be decorated with a stopping-off composition, these portions which are to be inlaid being left exposed. The stopping-off composition is applied by hand or by stencils or the whole of the surface is coated, and those portions which are to be inlaid removed with a suitable tool. The metal object thus prepared is then placed in an iron

FIG. 6.—Furnace for ornamenting and inlaying metallic surfaces.

receptacle containing the metal which is to be inlaid in a powdered form or subjected to metallic vapour by the process just described. If the zinc is the metal to be inlaid, zinc dust is the powder employed. When the article has obtained the desired depth of inlay and onlay, it is allowed to cool and then removed and brushed with a stiff brush to remove the stopping-off composition. A useful type of furnace for this class of work when using the zinc-dust vapour process is shown in Fig. 6, and a specimen of the results obtained in Fig. 7.

The vapour process enables a variety of effects to be obtained and a number of metals to be blended together

which hitherto has been impossible, and alloys of many colours and tints to be obtained in the one operation. The thickness and depth to which the metals are to be inlaid and onlaid can be controlled at the will of the operator. This vapour process of burning in and blending metals enables very beautiful colour effects to be obtained, the colours ranging from silver-white to yellow brass and bronzes of various shades graduating to red copper. A great charm about this new process of inlaying metals, and one that is unique, is that the inlay has not the sharp line of demarcation essential to damascening and similar processes, but a soft transition from the inlaid metal to the surrounding metal. For instance, in the case of inlaying zinc in copper, the zinc is surrounded by a band or halo of a golden-coloured alloy. This process of inlaying is not confined to zinc and copper; it has been successfully applied to such metals as nickel, cobalt, antimony, and aluminium.

In conclusion, I venture to express the hope that this new process of galvanising and blending metals may prove of some interest and benefit to the metal industries of England.

DISCUSSION.

The CHAIRMAN said he was much struck by the statement that this process was cheaper than the comparatively simple one of dipping, and that, as he understood, it was unnecessary that the articles should be carefully cleaned before being subjected to the process. He should like to know whether he had correctly understood the author in that respect, and also if it was a fact that the process did actually compete in point of cost with the ordinary one of galvanising. As he gathered the operation took several hours, during which a considerable temperature had to be maintained, and a certain amount of plant was necessary, all of which meant cost. It was also remarkable that there were two such distinct variants of the process, one in which zinc dust was used, and the other in which molten zinc was employed. In neither case was the temperature high enough to reach the volatilisation point of zinc, but he imagined that the passage of the hydrogen through the molten metal was essential for the coating of the articles where molten zinc was used. Although the author had stated that this was a metallurgical rather than a chemical paper, yet there was one special portion of the subject in which chemists would find matter for discussion, namely, a consideration of what was known as Preece's test as a suitable means of ascertaining the actual amount of zinc deposited on an article submitted for examination.

Mr. PHILIP said that the beauty with which extremely minute details of designs were reproduced by the zinc vapour process, as shown in the photographs exhibited, was astonishing. He was not able to grasp the author's meaning when he referred to the existence of some electric action as accounting for the deposition of the zinc on metal from zinc powder, heated below the vapourising point. He (Mr. Philip) suggested that this action was rather analogous to the passage of carbon into iron in the cementation process at temperatures far below the melting point of either the iron or the carbon. He agreed with the Chairman that it was astonishing that a method requiring so much special apparatus and so long a time for completion could compete in cost with the ordinary rapid hot galvanising process, but it was probably partly due to the fact that the cost involved in keeping large tanks of zinc melted for long periods and the depreciation of the tanks and of the zinc itself by absorbing iron, handicapped the older process, whilst, on the other hand, the new process was carried out at a temperature which did not affect the temper of steel, and permitted the zincing of accurately machined articles without their dimensions being sensibly altered, and thus possessed advantages over the old hot galvanising process, which could not compete with it in these respects. Mr. Cowper-Coles had found that Preece's test did not yield satisfactory comparative tests with the electro-galvanised iron and vapour galvanised iron. In his own experience he had found that electrolytically deposited zinc withstood Preece's test better than hot galvanised iron for the same

FIG. 7.—Copper panel inlaid with zinc.

weight of zinc per surface area, and he attributed this to the purity of the zinc deposit. Preece's test had to be very carefully carried out to be of any value. The article under test was plunged in a saturated copper sulphate solution at a temperature of 70° F. for one minute, it was then taken out and shaken in a rapid stream of water, if this removed all the copper deposit the test was repeated until an adherent layer of copper was obtained which could not be removed from the metal surface by running water. When this point had been reached the underlying iron or steel had become exposed, and the number of dips required to reach this point was a measure of the satisfactory protective nature of the zinc covering. The use of ferric sulphate solution as a substitute for copper sulphate in a modified Preece's test as proposed by the author appeared to him to be fallacious, for metallic iron itself reduced such a solution. The author stated that the vapour galvanised steel or iron did not resist Preece's test so well as hot galvanised or electrolytically galvanised material, but on the other hand it resisted corrosion due to rusting better, and he explained this as being due to the formation of a protective zinc-iron alloy on the surface of vapour galvanised articles. It was not clear whether this superior resistance to rusting of the zinc-iron alloys was an observed fact or was merely a theory. If it was a matter of experience it settled the question, but the formation of these zinc-iron alloys always took place on the surface of iron or steel galvanised by the ordinary hot process. The amount of iron present in such zinc-iron alloys ranged from a trace up to about ten per cent.

Mr. J. W. HINCHLEY said, having the technical supervision of this process in the United Kingdom, he might perhaps throw a little light on some of the points which seemed obscure. The author had described the processes as "vapour galvanising," but the greater part of the paper was concerned with the process known all over the world as "Sherardising," in honour of the discoverer of the process, Mr. Sherard Cowper-Coles himself. In the process of "sherardising," the vapour of zinc had, if any, a very secondary action. He could give numerous facts from practical working, and also from laboratory tests, to support this contention. To give one instance, in "sherardising" articles produced by "punching"—as was common in this country, punches were used which were not sharp, so that the fibres of the steel or iron were torn out, forming fine fissures—invariably those fissures were not "sherardised"; but there was no reason why they should not be, were the process a vapour process merely. The author had entirely neglected perhaps the most important consideration, the percentage of metallic zinc in the zinc dust: it was by regulating that, that the process became a commercial one and capable of control. The regulation of the temperature only was of no value, because the heat could not be controlled sufficiently exactly for practical purposes. He had been unable to get a deposit which was comparable to "sherardising" from vapour only. He could get a deposit, but which had not the slightest resemblance to "sherardising," and was practically and commercially useless, and further required an extremely high temperature for its production. As to the protective value of the process, five or six years ago, in its early days, pulley blocks were "sherardised" which had been in use in the open air ever since, and which were as good to-day as when they left the factory, with the exception of the wear and tear on the chains. They had been exposed every winter and summer to all changes in the weather. The question of cost was simple. A quarter of an ounce of zinc per square foot, applied to an article by the "sherardising" process, was more effective than two ounces applied by wet galvanising, so that the saving in zinc alone was enormous. Again, when properly carried out, the amount of waste was practically nil. During the last year at the Willesden Works the amount of zinc lost was only that occasioned by handling, and in the crannies of the factory, which was swept up and sold as sweepings. Other items of cost were the pickling of the goods and the putting into the drums. The pickling must be carried out far more carefully than had been suggested, and although in the laboratory it was possible to get a coating on greasy goods, they were always par-

ticularly careful to remove any oil, unless it were an extremely small amount, because, although it might not interfere with the process so far as getting a coating, it produced a bad colour and quickly spoilt the zinc dust for future use. The temperature required, depended largely on the character of the steel or iron; for cast iron it must be higher than for wrought iron and mild steel. "Sherardising" began at 160° C. with mild steel, but 200° C. was generally necessary for cast iron. There was another important point with regard to this process; it showed mechanical faults in the articles. If a bad weld were present, or a crack in a tube, the process showed the existence of these faults; so that he would suggest to engineers who wanted to be sure of permanence and excellent goods, that they should specify this process. Another interesting thing was that owing to the time character of the process, a slow rise of temperature followed by a slow cooling, the articles were extremely well annealed, and the result was that chains and such articles as were struck from a bar, or bolts or nuts which were struck in a machine and immediately cooled by a flow of water, were actually stronger and would stand work much better after the process than before. In fact, in the case of chains, and many other goods, the strength increased about 5 per cent. Springs also could be "sherardised" without their temper being affected, and large quantities of springs were so treated for exposure out of doors.

Mr. BRYAN CORCORAN said that in galvanising by the wet process the coating was apt to crack off and the surface was very easily rusted. He should like to know whether plates dealt with in this way could be bent better and whether wire could be woven, and especially whether wire so treated could be afterwards drawn so as to leave it with a good surface and a good coating that would not come off in the process of weaving.

Mr. WALTER F. REID said there seemed to be some doubt as to what it was that deposited the zinc on the surface of the iron. For the present, he preferred to take the opinion of the author, and to consider that the zinc volatilised; but the interesting problem was how did it volatilise? Did it volatilise because of the carbon monoxide that perhaps permeated the walls of the cylinder in which it was heated? That might account for the fact that the zinc did not deposit itself on the internal walls of the cylinder, which themselves were made of the same material as that on which the zinc was deposited. Another interesting point was the use of zinc dust for the purpose, which contained a certain percentage of oxide. They all knew that zinc dust, if not exactly a waste product, could, at any rate, be obtained at a lower price than spelter, and possibly that might obviate the increase of cost, if there were any, in the process. But there were losses in connection with the ordinary hot galvanising which ought to be borne in mind, for instance, the alloy of iron and zinc, which formed in that process, was clear evidence that the coating was more efficient than in wet galvanising, where no such intermediate alloy was formed. In the hot process one of the difficulties was that a large percentage of the alloy with iron might be formed if the temperature were kept too high. It seemed to him that the intermediate coating was not only protective to some extent, but it also made the zinc adhere as well as it did to the article. Mr. Corcoran was quite correct in saying that zinc deposited by the ordinary cold process was apt to flake off, which was, he thought, because that intermediate coating was not formed. With regard to the percentage of zinc oxide, he should like to ask the author if he had tried the maximum percentage of oxide which could be used, mixed with the metallic zinc dust. Zinc oxide was now being produced on a very large scale in Upper Silesia, and he had the pleasure of associating in some experiments there a short time ago, where zinc oxide was being produced in a very large quantity from the old residues of the mines. There were more than a million tons of these residues from which was produced an oxide of zinc, slightly contaminated with iron, and that percentage of iron rather reduced the value of the product, because it interfered with the colour when the zinc oxide was used for making paint. It seemed to him that in such a process as this, an oxide of that kind might be very well

available for galvanising, and could be produced very cheaply.

Dr. G. T. MORGAN asked whether zinc dust vaporised more readily than the massive metal, and whether at the temperature of the process zinc dust had any appreciably different vapour pressure to zinc itself.

Mr. COWPER-COLES, in reply, said the first question raised was that of cost. Undoubtedly, the cost of vapour galvanising was less than that of hot galvanising, the chief reasons being that no zinc-iron alloy was formed, and the whole of the zinc dust was consumed, and there was no waste. If the zinc dust deteriorated at all, it could always be renovated by the addition of carbon. The temperature required for vapour galvanising was very low as compared with hot galvanising; it never need exceed 600° F., and was quite workable even at 500° F. In the case of hot galvanising, a large mass of metal had to be kept molten day and night; the molten zinc was continually working on the iron tanks to form a zinc-iron alloy, which was only saleable at a considerably reduced cost. Another saving effected by vapour galvanising was that the cleansing had not to be carried out to the same degree of nicety as in the ordinary hot process or in electro-zincing. The next question raised was that of the temper of the articles treated and their elasticity. Among the specimens exhibited, would be found files and watch springs coated by the vapour process, which had not lost their temper in any degree. Specimens of iron plate which had been vapour galvanised and then rolled and drawn, were also exhibited.

With reference to the maximum amount of zinc oxide which could be present in the zinc and yet give satisfactory results, he had not the figures with him, but he had carried out experiments extending over many months, using the same zinc dust and adding only a sufficient quantity each day, to make good the actual metallic zinc vaporised. It was found that the zinc became more oxidised each day, as the drums were opened when the zinc dust was still hot. If he remembered rightly they found they could get good results with only 40 per cent. of metallic zinc present, although it took somewhat longer to obtain the same weight of zinc per square foot on the iron articles under treatment.

New York Section.

Meeting held at Chemists' Club on Friday, February 19, 1909.

MR. MAXIMILIAN TOCH IN THE CHAIR.

LITHOPONE.

BY HERMAN S. RIEDERER, PH.D.

The earliest reference which can be found for the production of lithopone, known also as Ponalith, Griffiths' White, Graves' White, and Zincolith, was J. B. Orr's English patent of Feb. 10, 1874, for an Improved Zinc White. Theoretically it is a molecular mixture of zinc sulphide and barium sulphate, but the products which are on the market contain other substances as well. The advantages claimed for it are, that it is not affected by sulphides and has high covering power, and its disadvantages, due to particular methods of manufacture, are, that on exposure to sunlight it often turns grey and becomes chalky.

To make it, solutions of barium sulphide and zinc sulphate are mixed in molecular proportions. The resulting precipitate of zinc sulphide and barium sulphate is then dried, heated in a furnace, ground, washed, and re-dried. The greatest care is necessary to obtain sufficiently pure solutions, as metals which form black or coloured sulphides would give the pigment a grey, yellow, or brown tint.

Barium sulphide is obtained by roasting ground barytes with coal or other carbonaceous material in a reducing atmosphere. Two types of furnaces are used, viz., flat bed reverberatory and rotary kiln (Bruckner); either is

equally good. Lixiviation of the product of the roasting gives a solution of sufficient purity for the next stage of the process.

For the zinc sulphate solution any zinc bearing material may be used. Spelter and dross leave little or no zinc in the insoluble residue, but zinc ashes usually leave so much mud in the solution tanks that the unit of zinc in this material is not so valuable. As regards impurities the sulphide metals cause little trouble. Arsenic and antimony either disappear as arsine and stibine where metallic zinc is used, or are precipitated with the copper and cadmium by adding some barium sulphide solution. Iron and manganese are usually removed by boiling with bleaching powder. A more powerful oxidising agent and longer boiling are usually necessary when manganese is present.

The two solutions in proportionate quantities are then mixed to produce the molecular precipitate, which is then filterpressed and dried. Vacuum dryers are now coming into use in place of hot air rooms. The dried precipitate is white, but lacks body; this is produced by the burning. Over-burning converts some of the zinc sulphide into oxide, which reduces the value of the pigment both as to strength and yield; under-burning gives a pigment without body. Some zinc oxide is always found in lithopone, but it should be kept below 2 per cent.; it ranges between 0.5 per cent. and 12 per cent. After the burning, the red hot pigment is at once quenched and ground fine, after which it is thoroughly washed, dried, disintegrated, and packed. Pebble mills are now being tried to replace the older buhr stone mills.

Ordinary lithopone contains about 29.5 per cent. zinc sulphide. A higher grade, containing from 45 per cent. to 48 per cent. sulphide, is produced by replacing part of the barium sulphide by sodium sulphide, and washing out the resulting sodium sulphate. Lower grades are also made by replacing part of the zinc sulphate by sodium sulphate.

There is much diversity of opinion as to why lithopone turns grey on exposure to sunlight, and many patents have been taken out for the manufacture of a light-proof product. But the real causes have not been definitely determined, though lack of purity in the product seems the most probable cause. Zinc salts other than the oxide and sulphide are often found, but 1 per cent. to 2 per cent. of these are not usually considered objectionable. The production of lithopone is increasing.

MANUFACTURE AND PROPERTIES OF MILD PROCESS WHITE LEAD.

BY DR. C. D. HOLLEY.

The "Mild process" for manufacturing white lead is the only one in practical operation in this country which does not require the use of acids, alkalis, or other chemicals in the process of manufacture, every trace of which should be removed from the finished product, necessarily involving certain purifying processes which in themselves are expensive and costly, and if incomplete will cause a marked deterioration in the quality of the lead produced. This process derives its name from the fact that it is the mildest, simplest, and most natural process possible for the manufacture of white lead—metallic lead, air, water, and carbon dioxide being the only substances required. There are no impurities to be removed, no off grade lead which must be blended in, or sold at a much reduced price, no by-products of any kind. This process results in the production of one uniform product, a pure basic lead carbonate of approved chemical and physical constitution and of a whiteness, density, and covering power not exceeded by that of any other make of white lead.

Numerous attempts have been made to reduce lead to a granulated form and then by attrition and agitation in the presence of water and carbon dioxide secure conversion into white lead, among which may be mentioned those of Welch and Evans of Philadelphia in 1814, in which granulated lead was placed in lead-lined barrels, which were made to revolve. The barrels were partly filled with water, and the particles of lead removed by attrition, were oxidised by oxygen from the air, and this

oxide carbonated by the introduction of carbon dioxide produced from burning charcoal; also that of Smith Gardner, of New York, in 1840, in which granulated or small pieces of lead were introduced into vessels lined with sheet lead, and partially filled with water, and so arranged that they could be revolved or manipulated in such a manner as to subject the lead to continual attrition. The vessels were kept closed, and during the process carbon dioxide and air were introduced. Owing to a lack of knowledge of the correct principles by which this process must be conducted, all of these earlier attempts failed, and it remained for Mr. Willson H. Rowley, of St. Louis, Mo., to put this type of process into successful operation on a large scale. Rowley conceived the idea of atomising or disintegrating the lead with the aid of a current of high pressure superheated steam, thus obtaining the lead in a very fine state of division, affording a very large surface for attack. His experiments were successful, and the several patents covering the processes of manufacture were granted in 1902 and 1903; and immediately thereafter a plant of about 1000 tons annual capacity was equipped and placed in operation. The product found immediate favour and a ready sale. In 1906 the process was taken over by the owners of the Acme White Lead and Color Works and a 10,000 ton plant was made in Detroit, embodying numerous improvements in machinery and equipment.

In this process the corroder is not obliged to use the extremely highly refined lead used in the Dutch process but may use an ordinary good grade of lead; some of hard grades of lead, however, do not suffer conversion as easily as the softer varieties, although there is apparently little or no difference in the colour and quality of the product obtained, provided the silver content is kept below 1 oz. per ton.

The lead is melted in large kettles holding about 5000 lb. each, from the bottom of which it is conveyed through heated pipes to the "atomisers," which are similar in principle to the ordinary laboratory blast lamp; in the atomisers the molten lead comes in contact with a current of steam superheated to a temperature higher than the melting point of the lead. The expansive force of the steam disintegrates the lead into exceedingly minute particles which, in the course of their descent, solidify. Each of the four atomisers in the present plant has a capacity of 1500 lb. of atomised lead per hour, or a combined capacity of 6000 lb. per hour. The streams of atomised lead are directed downwards in a large steel room or chamber two stories in height, in the bottom of which is about two feet of water. On the floor below the atomisers, about half way between the top and bottom of the blow chamber, is an opening through which a large spatula can be inserted so as to collect a small quantity of the atomised lead, so that the fineness of the particles can be readily ascertained and the atomisers regulated accordingly. Once the valves are correctly adjusted very little regulation is needed. By means of a drag and screw conveyor, the lead, in the form of a heavy soft mud, is delivered from the bottom of the blow basin or blow chambers, to the pump-feeder, which keeps the particles suspended in the water, so that the material can be readily and conveniently handled by a rotary pump, which forces the lead and water through a pipe line to the float boxes, where the lead is deposited in the desired compartments; these, having a higher level than the bottom of the blow chamber, are piped back, so that the water returns again to the blow basin, which insures against any loss of lead. There are five float boxes in each of the two lines, and when filled each line has a capacity of 250,000 lb. of atomised lead. By means of gate valves the lead is discharged into the oxidisers directly underneath, 6000 to 10,000 lb. to the oxidiser as desired. The requisite amount of water is added, a current of air under low pressure from a fan introduced, and the contents agitated mechanically for 24 to 36 hours. The particles of lead during the atomising process have already become coated with a thin pellicle of suboxide, which renders the lead very active chemically, so that within a very few hours after the beginning of the agitation a strong chemical action sets in, accompanied by a marked rise in temperature, resulting in the formation of any of several

basic lead hydroxides as may be desired, which will vary in colour from greenish yellow, through the different shades of yellow, orange, to a brownish orange; these results are secured by varying the amount of water, air, agitation and control of the temperature. Some of these basic hydroxides are much more suitable for white lead making than others. At the expiration of 24 to 36 hours, according to the size of the charge, about 80 per cent. of the lead will have been converted, and the oxidisers are discharged into a trough emptying into the float system on the floor below where, by means of an inclined drag, two agitator tubs, and a float-table, the metallic lead is completely separated from the basic oxide, automatically conveyed to the small pump-feeder, from which the pump returns it to the float boxes, there to be added as a small increment to fresh charges of atomised lead in the oxidisers, which secure a practically complete conversion of the returned lead. The separated basic hydroxide, after flowing over the table, runs into a tank, from which it is conveyed by means of another rotary pump to the fourth floor, where it is deposited in a series of large tanks, the water being returned to the separating system, thus avoiding any mechanical loss of lead. The above-mentioned tanks also act as a storage for the basic hydroxide which is drawn as required into the carbonators located on the floor below, it having been reduced to the desired consistency. The carbonators are large wooden cylinders somewhat similar to the oxidisers in construction, but of less capacity; in them the basic lead hydroxide is agitated in the presence of carbon dioxide, which, by means of scrubbers, has been thoroughly cooled, desulphurised, and freed from soot particles.

The carbon dioxide used, is produced by the combustion of a selected grade of coke, very low in sulphur and volatile matter. The furnace is so constructed that 90 to 95 per cent. of the oxygen of the air entering the grate is converted into carbon dioxide, and the combustion so controlled that there is practical absence of carbon monoxide. The efficiency of the furnace is therefore very high. The heat produced is utilised as indicated in assisting the production of steam for power purposes. The gas drawn from the furnace by the fan, passes through a cooling chamber, then up through the scrubbing towers, two and one-half stories in height, which cool the gas to room temperature and free it from any traces of sulphur dioxide and hydrogen sulphide, in a manner similar to that used in the purification of illuminating gas. The gas as it comes from the top of the towers is thoroughly freed from all impurities, and has a carbon dioxide content averaging 19 per cent.; it is conveyed to the carbonators through a large pipe with a lateral branch to each carbonator. During the first 18 hours, no apparent change is noticed in the colour, but during the next 18 hours the change is very rapid and is accompanied by a considerable increase in volume of the mass, the carbonators requiring to be watered at short intervals, both on account of the swelling of the mass and the chemical combination of the water with the lead. In approximately 36 hours the carbonation is complete, resulting, if the operation has been properly conducted, in an exceedingly white, basic lead carbonate of very nearly the theoretical composition. As there are no impurities present, no washing or floating is necessary, and the thin semi-paste mass is drawn from the carbonators by the pump and pumped directly on to the drying pans and dried in the usual manner. When dry, the white lead crumbles instantly under the slightest pressure into a very fine amorphous powder.

The "Mild process" is under a much more complete control than any other process, as any slight variation that may take place in the chemical actions involved can be easily corrected and counterbalanced. The gas is tested at regular intervals, and the changing conditions of the lead carefully noted. The completion of the carbonation is very clearly indicated by certain distinctive characteristics of the lead and its behaviour at that time, so that, contrary to expectation, there is no danger of over-carbonation under competent supervision.

At first sight it might seem that a white lead produced in the manner described would consist largely of a mechanical mixture of hydroxide and normal carbonate,

but such is not the case, as may be demonstrated both by a microscopical examination and by a study of the process of formation of the white lead. The composition of the hydroxide formed in the oxidisers indicates a hydration of 10 to 12 per cent., or only about one-third of the combined water to be found in the finished white lead. Therefore, the larger part of the hydroxide portion of the white lead molecule is formed during the carbonating process, and has much to do with the large apparent increase in volume exhibited during the carbonating, which in itself serves as a close check on the completion of the carbonation.

From a manufacturing standpoint this process has much to commend it, especially as regards the following items:—The process is not restricted to a specially refined lead; it is under complete control: it results in conversion into white lead of all of the lead entering the process, avoiding any ultimate metallic residues whatsoever; the white lead obtained is of a uniform grade with no tailings, sandy or crystalline lead being produced; there are no mechanical losses of lead, as the same volume of water is used over and over again. Manual labour is reduced to a minimum, the conveying of material in the process being accomplished entirely by gravity and pumps. The workmen do not come in contact with the lead either through handling or from dust in any part of the process from the time the pig lead is put into the melting kettle until the white lead is removed from the pans.

The white lead produced by this process is very similar to that produced by the older process as regards the amount of oil thinners required for grinding and for reducing to painting consistency. Under the brush it works more easily than any other white lead.

Practical experiments, in which different kinds of wood, painted with three coats various brands of white lead, and exposed for two years, indicated the superiority as regards covering power of "Mild process" white lead: as regards opacity of the coating, all appeared to be of equal merit after three coats had been applied. As compared with other white leads, "Mild process" is of equal whiteness, and the particles are of a very uniform fineness. Although very soft and chalky in appearance and "feel," "Mild process" lead is as dense and does not require any greater quantity of oil in the grinding and little, if any, more in reducing to painting consistency than other leads. Under the brush it works very easily, and owing to the uniform fineness of the particles it covers a large amount of surface with great opacity, and its entire freedom from lead acetate and other impurities ensures for it a maximum wearing or service value.

DISCUSSION.

In reply to a number of questions,

Dr. HOLLEY said he had found hydrated hydroxides containing as little as 2 per cent. of lead hydroxide, and some as high as 24 per cent. Some of them could not be converted into white lead; that is to say, the product would be pink, instead of white. The essential part of the process was to cause hydration. If the carbonation were forced too rapidly incomplete hydration took place.

Measurements made by Dr. Knap, of Chicago, indicated that the particles were very small and more uniform in the "Mild process" sample than in the "Old Dutch process." There was no more pressure during carbonation than could be produced by an ordinary fan, possibly three or four ounces. During certain stages of the process, when the carbonators were at 55°–58° F., the gas entered with a 19 per cent. carbon dioxide content and came out with 4 per cent. or 5 per cent. of carbon dioxide. In the latter part of the process, the gas entering at 19 per cent. will come out 16 per cent. or 17 per cent., when the temperature in the carbonators ranged from 98°–103° F. The reason for this was that the carbon dioxide did not act by contact on the lead particles, but by being dissolved in the water, wherefore the amount dissolved by a warm carbonator was very slight. They were using a great deal of Missouri pig lead, and also what might be regarded as "corroders" lead; they were not inferior grades of lead, nor did they contain any considerable amount of impurities.

SUBLIMED WHITE LEAD.

BY L. F. HUGHES.

In describing a product in the manufacture of which we are personally engaged, it is perhaps difficult to avoid making an *ex parte* statement, but it appears to me that this attitude should be as far as possible avoided. If, therefore, I say little or nothing in praise of sublimed white lead as a pigment, it is because my purpose is not to advertise or extol this or any material, but merely to submit the essential chemical and physical data of its manufacture and properties.

Lead sulphate when finely divided and submitted to the action of an oxidising flame undergoes an abrupt combustion directly to the basic sulphate of lead, $2\text{PbSO}_4 \cdot \text{PbO}$, which passes off as a vapour, and if conducted through a super-heated chamber can be maintained in a state of gaseous dissociation. Upon condensation it appears as an intensely fine, white powder, non-crystalline even under the polarising microscope (a marked difference from the lead carbonate pigments), and highly opaque. The reaction resulting in the production of this compound was discovered by E. O. Bartlett, a zinc oxide manufacturer, about 1866, and was by him developed into a commercial process, briefly as follows:—

Pulverised galena is fed into an open coke fire, and the furnace gases and fumes are drawn into a series of settling chambers in which the dust and non-volatile impurities are deposited. Draught is supplied by a suction fan placed at the farther end of the settling and cooling pipes and through this fan the now condensed and purified fume passes and is delivered into an ordinary cloth filter system or "bag room," very similar to those used in the manufacture of zinc oxide. The settling and cooling train employed in actual practice is about 1000 feet in length with an average internal diameter of about eight feet. It is in part exceedingly narrow and is in places distorted into abrupt curves with interrupting "baffles." The development and elaboration of this purifying train proved in practice a most intricate problem and it was largely worked out by actual change and experiment. A discussion of the developments and the phenomena disclosed by these experiments would be very interesting, but the manufacturers naturally feel that these are trade secrets.

As the ores used contain no volatile bases in addition to the lead, except a little zinc, the pigment collected on the filter screens requires no subsequent treatment, and it is packed directly from the "bag room" hoppers. The composition of sublimed lead as it exists on the market varies from the theory in two ways:—(1) It contains as an admixture a little zinc oxide from the combustion of sphalerite in the ore. (2) It contains somewhat more sulphur than accords with the formula $\text{Pb}_3\text{S}_2\text{O}_6$. The latter variation is due to a secondary reaction from the oxidation of free sulphur dioxide in the furnace flues. A portion of this gas is converted into sulphur trioxide and combines with the basic compound, probably converting its equivalent into the neutral salt. This secondary reaction can be avoided, but it has not so far proved commercially advantageous.

The commercial product has a specific gravity of 6.2, and diameter of particle of $1/35,000$ th inch. Its analysis varies within narrow limits: it consists approximately of lead sulphate, 75 per cent.; lead oxide, 20 per cent.; zinc oxide, 5 per cent. There should be no other bases present save in traces. There have been frequent assertions that the lead oxide present is free litharge, but as this statement has been completely refuted by competent and disinterested investigators, it is unnecessary to do more than cite the fact of the assertion and its incorrectness.

At present, sublimed white lead is, I believe, made only in the United States. There have been several sporadic attempts to conduct its manufacture in Great Britain, but they have been unable to maintain the rather delicate adjustment of furnace conditions which alone yields a white pigment by this process. As an instance of the unfortunate efforts made abroad, I will mention that one concern, at least, abandoned all endeavours to purify the sublimate mechanically and resorted to digestion with sulphuric acid to dissolve out the discolouring

impurities. This treatment did produce a white pigment, but it destroyed three of the chief essentials of quality in a pigment: fineness, basicity, and opacity.

So much for the production of the material in its dry form as the paint manufacturer receives it. In a paint it exerts no extraordinary or characteristic influence; and this fact might be predicted from its chemical nature. Chemically it may be regarded as entirely inert in the mix, and it is therefore almost free from the action upon tinting materials which characterises the chemically unstable lead pigments. For the same reason it is highly resistant to the action of gases, even hydrogen sulphide having little discolouring effect upon the paint coat under service conditions.

The extreme fineness of division which characterises all amorphous sublimates gives sublimed white lead an advantage over mechanically ground or precipitated pigments in that it stays in suspension better. This same fineness necessitates a very thorough grinding unless the paint contains a proportion of coarser particles. A loose mill will do no more than separate the pigment into tiny aggregates encysted by oil—a condition not conducive to either smooth working or durability. An appreciably coarser pigment in the mix, however, effects an easy and complete dispersion of the particles. This quality of fineness, however excellent in effecting the production of an impervious and durable coat, is found somewhat objectionable from a commercial standpoint. Some painters have a preference for a paint made with only one pigment, and no amount of demonstration will convince them that the addition of another ingredient is for the purpose of improvement. Now, as has been well pointed out by one of our best chemists, a paint coat is better made with three sizes of particles than in any other way. It brushes better, takes naturally a more uniform thickness, and, he considers, offers a more nearly impermeable layer. In a sublimate there is, of course, only one size of particle, and for that reason a straight sublimed white lead paint does not brush so easily as one containing from ten to fifteen per cent. of a coarser material. This admixture may be fibrous magnesium silicate, silica, or Dutch process white lead; named in the order of their influence on the brushing character of the mix. It is quite true that the straight pigment makes a good paint, and some grinders are putting out the single pigment in oil; but I believe such a mixture as I have suggested or, better still, one containing a small addition of zinc oxide to give hardness to the coat, is better than the straight paint. There is not, in my opinion, any pigment which for general work gives the best results when used alone. Straight zinc oxide is too fine and makes a very hard coat; sublimed white lead is also too fine; lead carbonate is chemically too unstable; and so through the entire list of painting materials, we find for each substance certain deficiencies which can be remedied by addition of other ingredients possessing the particular characteristic desired. This property of fineness is no detriment. The finer the better is an invariable rule for the major pigment in any paint, but there is an undoubted advantage in having present a minor proportion of coarser particles. The selection of the particular type of coarse particle

is a matter for the judgment of the paint compounder, but it is worth notice that those mixtures which are generally giving the best service are characterised by the presence of a crystalline ingredient of sharp angularity and chemical stability. The function of crystalline pigments has of late been a subject for discussion in legislative as well as technical circles, and it is evident that it has not received the careful consideration which it deserves even among paint men. Otherwise, it is hard to account for the opposition to materials on the ground of crystallinity by advocates of corroded white lead, when besides the presence of visibly angular fragments of cerussite, that pigment shows itself anisotropic to polarised light and must therefore be regarded as entirely crystalline. It is quite true that a paint made from coarse crystals only will not give satisfaction, but it is equally true that no entirely amorphous substance exhibits perfection.

This apparent digression from my text was for the purpose of supplying a possibly superfluous explanation of my advocacy of the valuable but much abused reinforcing pigments.

To summarise, it may be said of sublimed white lead that it is characterised by extreme fineness, chemical stability, high opacity, and is unique among lead pigments in that it is amorphous. Paint coats made from it alone or without any large admixture of chemically unstable compounds are noticeably free from discolouration and exhibit a characteristic wear from the surface without development of cracks or checks. Its faults have been elaborated above.

DISCUSSION.

MR. G. W. THOMPSON considered that "Sublimed lead" was the proper name for the product and not "Sublimed white lead," as it was called by the author. White lead could be used alone as a pigment; sublimed lead could not.

MR. EVANS replied that the product was lead, as Mr. Thompson had said, that it was white, and was sublimed. The Picher Lead Co. also made a blue product, which was sublimed, called "Sublimed blue lead." The white paint had been called "Sublimed white lead" since the inception of the company, thirty-five years ago.

Meeting held at Chemists' Club, on Friday, March 19th, 1909.

MR. MAXIMILIAN TOCH IN THE CHAIR.

DUTCH PROCESS WHITE LEAD.

BY G. W. THOMPSON.

The general method of manufacture of "Dutch process white lead" has been so fully described that it is unnecessary to further describe it, but certain points in connection with its manufacture deserve consideration.

Corroding Pig Lead.—In the Dutch process a very pure pig lead is needed, as the more objectionable impurities are not eliminated to an appreciable extent at any step in the process of manufacture. There are few, if any, metals that can be found in commerce as pure as the best grades of corroding lead. This is shown in the following table:—

COMPOSITION OF AMERICAN PIG LEADS.

	South-East Missouri undesilverised.	South-East Missouri desilverised.	South-West Missouri undesilverised.	Ordinary common.	Ordinary corroding, or refined.

Silver and copper are the most objectionable impurities in corroding pig lead: neither of them should exceed 0.0010 per cent. By zinc desilverisation—the Parkes process—both silver and copper are removed well below this limit. Bismuth is not removed by the Parkes process, but can be eliminated by the electrolytic or Pattison processes. Bismuth, however, only occasionally imparts a gray tint to white lead containing it. Iron does not alloy with lead appreciably, so that, in melting pig lead to cast it into buckles, the iron, which may have been present in the pig lead as a mechanical impurity, is eliminated. The maximum solubility of iron in lead is about 0.0015 per cent.

While a very pure pig lead is needed for the manufacture of white lead by the Dutch process, this does not necessarily operate against the process as an element of cost, as the refining of lead is a desilverising process—the silver recovered generally paying for the cost of refining.

Acetic acid.—The amount of 28 per cent. acetic acid used in the corrosion of white lead by the Dutch process seldom exceeds 1 per cent. of the lead set. Some of this acetic acid is carried away in the flue gases and is lost, some is eliminated in the wash-water, and the remainder stays with the white lead, combined in some form of insoluble acetate. Ordinarily, the amount of acetic acid present is about 0.08 per cent. There is no evidence, based on practical experience, that this acetic acid is objectionable. There is strong evidence that a very much larger percentage of acetic acid may be present without appreciable injury to the product. Very carefully conducted painting tests, which have been made by me, show no difference in durability between the ordinary Dutch process white lead and one to which lead acetate equivalent to 0.5 per cent. of glacial acid, had been added.

Fermentation.—The oxidation of the tan bark in the early stages of the corroding action is due to fermentation produced by micro-organisms, but when the heat has reached a certain point, the oxidation is in the nature of slow combustion in which micro-organisms have little or no part.

Pulp-mixed white lead.—White lead in water can be mixed with linseed oil, with the result that the oil displaces the water and combines mechanically with the white lead. The basis of pulp-mixed white lead is that its manufacture is more sanitary than dry grinding. It is somewhat whiter than dry-ground, because there is less overheating in the mills, and some of the mechanical impurities, such as tan bark, etc., go off with the water eliminated. The amount of water left in pulp-mixed lead seldom exceeds 0.5 per cent., and usually is much less than this. There is no evidence that this water injures the paint prepared from it, nor that pulp-mixed lead is inferior in any respect to the old-fashioned lead ground in chasers and then through burr mills. There is evidence, on the other hand, that pulp-mixed lead is equal in all its qualities to dry-ground, and, in addition to that, it works somewhat better for "flat" work inside.

The name white lead applies properly only to a compound consisting of lead carbonate and hydroxide in chemical union, or $2\text{PbCO}_3 \cdot \text{Pb(OH)}_2$.

The evidence that there is a definite compound of this composition is found in the following facts:—

If carbon dioxide is passed into a solution of basic lead acetate, a precipitate is obtained which, at first, may contain a large percentage of basic lead acetate in more or less insoluble form. As the solution becomes more nearly neutral, however, the composition of the precipitate approaches that given above. The basic lead acetate which has been precipitated with the white lead is dissolved in the more nearly neutral acetate solution. The indications are that the chemical process in the corrosion of white lead by the Dutch process involves, at the start, the oxidation of the lead and the formation of basic lead acetate; that this basic lead acetate is decomposed by the carbon dioxide present, the basic lead being precipitated as white lead, and that

the neutral lead acetate again acting upon more metallic lead is changed into the basic form ready to be acted upon again by carbon dioxide. The precipitation of white lead, therefore, from solutions of basic lead acetate corresponds to the formation of white lead in the stacks after the metallic lead has become oxidised.

Any one who is familiar with the Dutch process of corrosion can, on visiting the corroding stacks, isolate definitely, to his own satisfaction, white lead of theoretical composition. His examination of white lead in the stacks is similar to the examination of the mineralogist who selects pure crystals, which he analyses and finds to have definite composition. Other formulae for white lead have been suggested, but apparently only by those who have analysed commercial samples and who have not been familiar with the process itself. It is true that commercial white leads may contain a higher percentage of lead carbonate than that shown by the theoretical formula; this is due to the fact that the corroding operation is not under complete control. At times, carbonic acid will be in excess, and it will then in the conditions in which the white lead exists, act upon the white lead, converting it to neutral carbonate.

There is no evidence that a limited excess of lead carbonate in white lead is objectionable. Some advocate a percentage higher than the theoretical. It would appear proper, however, that some reasonable limit should be placed upon this excess. What this limit should be can be determined only by thorough physical and practical tests.

It is thus apparent that white lead is not a mechanical mixture of lead carbonate and hydroxide. It is possible that lead hydroxide can be mixed with lead carbonate and be made to combine, but there is no evidence that the properties of white lead are the properties of the two constituents separately considered.

The question has arisen as to the proper chemical name for white lead. It may be questioned as to whether it is desirable in all or many cases to use chemical names for commercial products. Commercial products are seldom even approximately composed of a single pure chemical constituent, and by using a chemical name for a commercial product we presuppose approximate purity. Chemists, of course, in making their analysis, obtain chemically pure precipitates, etc., but, in the case of mechanical mixtures, the results obtained by analysts are of value in proportion as they are expressed in percentages of the original proximate constituents, and, in so far as possible, in commercial terms.

Now, especially is this true in the case of white lead, for there is no thoroughly satisfactory chemical name current for even pure white lead. The most common name is "basic lead carbonate," but this is not satisfactory in that it is not sufficiently descriptive. It is possible to have anhydrous basic compounds. The name "hydrated basic lead carbonate" is equally unsatisfactory for the reason that the word "hydrated" may refer to water of crystallisation, as in the case of so-called "fully hydrated calcium sulphate." Probably, the best name for chemically pure white lead is "lead monohydrate dicarbonate," which is exceedingly cumbersome and not likely to be substituted for the simple name, white lead, which will probably continue to be used as answering all practical purposes.

The value of white lead as a pigment.—Some of the reasons that have been assigned for this superiority of white lead are untenable. The commonest is that it enters into combination with linseed oil, forming a lead soap, and that this gives it its working qualities. As a supplement of this theory, it has been asserted that it is the lead carbonate that gives to white lead its body. There is little ground, however, for the belief that white lead combines with linseed oil, except to an almost inappreciable extent. Hannay, some years ago, found that he could extract from white lead paste practically all the linseed oil it contained in its original form. Hannay's work has been repeated by me on many occasions, confirming his results and conclusions. It is true that white lead can be made to react on linseed oil at about the boiling point of water, but even then the reaction is only slight, unless the heating is prolonged

for some time. White lead contains about 31 per cent. of lead hydroxide. Figuring from the saponification value of linseed oil, which we put at 190, 100 lb. of white lead would require 76 lb. of linseed oil to combine with this lead hydroxide. It is seen therefore, that, in a white lead paste containing 10 per cent. of linseed oil, there is a large excess of base which should insure the complete saponification of the oil if such a reaction did take place.

On extracting white lead paste with ether, it is found that the linseed oil obtained contains a very small percentage of lead. The lead soaps obtained by precipitating the fatty acids of linseed oil with a lead compound dissolve readily in ether, with the exception of the lead soaps of the saturated fatty acids, so that practically all lead compounds would be dissolved by the ether. White lead adds to the drying qualities of linseed oil with which it is ground to the extent of this very small amount of lead, which combines with the linseed oil and dissolves in it.

As linseed oil paste does not show a combination of the white lead with the linseed oil, so it is also found that where an excess of oil is used there is no appreciably greater amount of combination between the lead hydroxide present and the linseed oil. Whether there is any combination between oxidised linseed oil and white lead after a paint has been applied is not definitely known. We have, however, no evidence that such a combination takes place, and it seems improbable that it does.

The conclusion thus is, that white lead is a relatively inert pigment, entering into combination to only a slight degree, if at all, with linseed oil or any of its constituents, when mixed with it as a paint.

The merit of white lead is largely due to its physical qualities. White lead has a remarkable latitude in the amount of oil it will take for thinning, so that it can be worked stiff or thin as the conditions demand. Its fluidity apparently increases the more it is brushed. This describes its working qualities. When thinned properly for painting it has a covering power greater than that of any other single white pigment.

The physical qualities of white lead are, to some extent, disclosed by a microscopical examination. This microscopical examination cannot be satisfactorily made unless the particles are first classified according to their sizes. We have been successful in constructing a classifier in which we can divide the particles up into groups, differing in a regular manner from each other in size. This classifier is a floating apparatus in which the particles are subjected to floating with successively varying speeds. The floating medium selected has been kerosene, on account of the high wetting power it possesses. In the apparatus which I have used, the particles float through four cones, which increase regularly in size, so that the diameters of the particles which settle out in these cones should vary regularly in size. This classification is, of course, not absolute, but it gives good practical results.

Dutch process white lead is composed of particles varying in size to an infinite degree.

It would lead too far to discuss the general question of the physical characteristics of a good pigment. Arguments, however, have been advanced to the effect that the pigment in a good paint should be composed of three sized particles. The theory is that the mixture of pigments having three different sized particles has the lowest percentage of voids. Good reasons have not been given, however, for assuming that the variations in size of particles should be limited to three. It is found that, taking spheres, an equal number of three different sized spheres can be figured out as giving a lower percentage of voids than where one size of sphere only is used, but unfortunately, it is found that those three sizes of spheres

differ from each other in their individual volumes as shown in the following table:—

Diameter.	Volume.	Per cent.
1.0	1.0	92.39
0.4142	0.0710	6.56
0.2247	0.0113	1.05

A pigment made up of 92 per cent. of comparatively coarse particles, 6 per cent. of medium sized particles, and 1 per cent. of comparatively fine particles would, in practice, hardly make a good paint. No calculations, as far as I know, have been made as to what still smaller sized spheres would have to be in order to still further reduce the voids. The indications are, however, from the study of those figures, that, in the case of spheres, an infinite variety would give the greatest reduction in the percentage of voids.

In conclusion, we offer this theory for consideration:—The pigment, the particles of which tend to fit together so as to give the smallest percentage of voids, is, *other things being equal*, the best pigment. Inventors of white lead processes have not recognised this sufficiently, and, for that reason, the many attempts that have been made to make a white lead to take the place of Dutch process white lead have been unsuccessful and wasteful of time and money.

DISCUSSION.

The CHAIRMAN said that what Mr. Thompson had said concerning the three sizes of pigment in a paint, producing the best results, originated some months ago, in the U.S. Paint Manufacturers' Association, which published a pamphlet to demonstrate that a film of paint should be composed of three sizes of grain, in order that the stress and strain of the film might be of greater value. Concrete was composed of three sizes of grain, and the assumption was that the strength of the concrete was due to the three sizes of its constituents. This was not borne out, as concrete was not composed of three sizes, for the larger pieces of aggregate, such as broken stone, were put in to concrete merely for economy's sake, and added no strength. Furthermore, the broken stone of the third aggregate in concrete might be composed of one hundred different sizes, ranging from 200 mesh up to 2 in. or 3 in. in diameter, and it was fallacious to argue from that analogy, that a paint film should be composed of three different sizes of grain in order to produce the best results. The strength of a film of white lead might be due to the variability of its grains, but there was no comparison between the structure of a film of paint and the structure of concrete.

THE INFLUENCE OF CHEMISTRY ON THE UTILISATION OF QUEBRACHO.

BY E. C. KLIPSTEIN.

The story of quebracho is one of the most remarkable in the annals of industry. Thirty years ago the word "Quebracho" was practically unknown, and only a few tanners in France and the Argentine Republic understood imperfectly the properties of quebracho wood. To-day it has forced itself into the tariffs of nations; millions of dollars have been invested in the manufacture of quebracho extract and in steamships for its transportation, while the civilised world is walking on quebracho tanned leather. This wonderful development is due to two facts: First, that the entire wood of the quebracho tree (not the bark only) yields from 18 to 20 per cent. of tannic acid, thus rendering the supply so enormous and its manipulation so easy as to make it the cheapest known tanning material. Two quebracho logs, weighing one ton each, will yield 1,200 lb. of an extract that will tan as much leather as the bark from five acres of hemlock timber (taking the percentage of tannin in hemlock bark as 8 per cent). Secondly, the discovery of a chemical treatment of quebracho tannin which makes it equal to the best vegetable tannic acid known. In consequence of this important discovery quebracho extract so treats

has become not only the cheapest but also the best tanning material known, and the standard of value for all other tanning materials.

"Quebracho" is a Portuguese word meaning "axe-breaker," and was applied to the tree on account of the extreme density and hardness of its wood. The species furnishing the extract is the Quebracho Colorado (*Loxopterygium Lorentzii*). It flourishes in Central South America. It does not grow in continuous forests like oak and hemlock, but stands alone or in groups surrounded by other hardwood trees, above which its peculiar "V" shaped top or crown towers many feet, forming a distinctive feature of the landscape, quite characteristic of the Chaco. These groups or clumps of trees, called in Spanish "Islands," extend for miles in strips, separated by much wider strips of alkaline prairie, covered with coarse grass. These alternate strips of woodland and prairie extend in a uniform north-easterly direction, like the Alleghany Mountains, from the Province of Santa Fé through the Grand Chaco of Argentina into Paraguay and Southern Brazil. Owing to this peculiar disposition of the forests, transportation becomes the most costly and difficult part of quebracho lumbering operations. The logs must be hauled long distances, in wagons drawn by oxen, through a roadless wilderness, sometimes as far as twenty miles, to the nearest factory or railroad or landing on the Parana River or its branches. The best organised extract plants have built narrow gauge railroads from a port on the Parana across the strips of woodland for fifty miles into the wilderness, in order to lessen the cost of transportation. It was the high cost of transportation which forced the building of extract plants in subtropical alkaline prairies from 600 to 1000 miles north of Buenos Aires. It was cheaper and more rational to transport machinery and skilled labour six thousand miles from Europe to the Chaco, and thereby have only one ton of extract to transport the same distance back, than to pay freight on four tons of wood over the same distance for the purpose of making one ton of extract in Europe or in the United States.

According to an Argentine legend, the use of quebracho for tanning leather was discovered by a German tanner in Buenos Aires. Observing that the water near a saw-mill was coloured red by the quebracho sawdust, it occurred to him that this might be due to tannic acid. Experiment proved the correctness of his supposition, and he became the first quebracho tanner. However this may be, in the month of April, 1875, a French firm in Buenos Aires shipped a sample log of quebracho to E. Dubose, the well-known dye-wood extract maker of Havre, France. In November of the same year, Dubose imported eleven logs more for further experiment, and the following year took out a French patent for quebracho extract as a substitute for catechu, gambier, etc. He at once began a propaganda, which finally resulted in the introduction of quebracho extract as a tanning material in France, Germany, Russia, and other countries of Europe. In 1883, Dubose induced the writer to bring over samples of quebracho extract to the United States, but without results, owing to its high price as compared with hemlock extract. On a subsequent visit to Dubose in 1887 he was so enthusiastic about the new extract that it was decided to make a second attempt to introduce it into the United States, but without success, because it could not be sold at 6c. per lb. against hemlock extract at 2½ c. Five years later, in 1892, a third and successful attempt was made, and the price having gone down to 5c. for the liquid extract, we succeeded in establishing the use of quebracho in the United States. Meantime, Casado, a wealthy land owner of Paraguay, erected the first extract plant in South America. He was followed by H. Renner & Co., in Hamburg, Germany, and by several other small plants in France and Germany, and finally by a second small plant at Peguabon on the Parana River in Argentine. All these plants were small, the quantity of extract produced was also small, but more than sufficient to keep up with the slow progress of extending its use, as was proved by the fact that Casado discontinued operations. A consignment of a few hundred tons made by Casado to a firm in New York about the year 1893 remained largely unsold until 1898. It is safe to say that the world's annual production of

quebracho extract between the years 1890 and 1897—twenty years after its introduction—would not equal one month's consumption of the United States alone at the present time. In the year 1895 a contract was made with H. Renner & Co., of Hamburg, for 150 tons of liquid extract at the low price of 2½ c., duty paid in New York, but the tanner to whom the extract was resold suddenly cancelled his orders because the finished leather had turned red in the warehouse, and there was great difficulty in finding buyers for the balance of the contract. This slow and halting progress in the use of quebracho extract was due to the peculiar character of its tannins. It contained an unusually large proportion of "resinous and difficultly soluble" tannins, called by chemists "insolubles," and an unusually small proportion of non-tannins, almost totally lacking in glucosides. Furthermore, its soluble tannins differed from those of oak and hemlock in that they were much more sensitive to changes of temperature and were readily precipitated by the sour liquors of the tan-vat. As is well-known, tannins are complex bodies existing in all plants. The tannins of no two plants are alike and even the tannins of the same plant vary greatly as to solubility in water. When tan-barks or tan-woods are treated with boiling water, and the extract is cooled down to the temperature of the air or cold water, all those portions of the tannic acid which are "difficultly soluble in cold water" fall out of solution as precipitates and are technically termed "insolubles" or "reds." The scientific name for them is "phlobaphenes" or tannins, which are resinous and soluble in warm or boiling water, but not in cold water, and therefore not available for producing leather. In consequence of this fact, every chemical analysis of a tanning material must show three things, (1) the "available" tannin which remains soluble in cold water; (2) the "non-tannins" or soluble salts and glucosides; (3) the "reds" or insolubles. All three of these constituents play a rôle in the tanning process. The available tannins combine with the hide substance to produce leather. The non-tannins ferment to form acids, which make the tan liquors sour and swell up or "plump" the hide so that the available tannins can penetrate the hide substance to form leather. This plumping effect is absolutely necessary. Finally the "reds" or insolubles, when not too great in quantity, are so held in suspension by the non-tannins that they are carried to a slight degree into the surface of the hide and render the leather firm and impervious to water. Now the proportions of these various constituents vary greatly in different plants and consequently in different tanning extracts. By the ordinary method of analysis a solid valonea extract, showing 64 per cent. of soluble tannin, will also show 25 per cent. of non-tannins and only 1.25 per cent. insolubles. By the same analysis, liquid extract gives soluble tannins 26 per cent., non-tannin 41 per cent., insolubles only 0.50 per cent. On the other hand, ordinary quebracho extract, containing 64.50 per cent. soluble tannins, will only show 7.50 per cent. non-tannins, while the insolubles amount to 8 per cent. or more than one-eighth as much as the soluble tannins.

A perfect tanning material, that is, a tanning material such as hemlock bark, which, by itself, will produce leather, contains nearly as much non-tannins as available or soluble tannins—more specifically, hemlock bark contains 8 to 10 per cent. soluble tannins and 6 to 7 per cent. non-tannins. The proportion of non-tannins is large enough to furnish, by fermentation, sufficient acid to plump the hide for absorption of the soluble tannins.

Quebracho wood, on the other hand, contains 20 per cent. soluble tannin, and only 2½ per cent. non-tannins (composed chiefly of soluble salts), and is totally wanting in glucosides. Quebracho liquors, therefore, do not sour and in consequence cannot be used alone for making leather. It is absolutely necessary to mix quebracho with some material containing a large proportion of non-tannins in order to get the acidity necessary for plumping the hide, and it was at this point in the use of quebracho extract where the trouble began in practice. It was found that when mixed with the acid liquors resulting from other extracts a large proportion of the soluble tannins were precipitated, together with all the "reds" of the quebracho, as a sticky slime on the hide. This slime hindered the

penetration of the tannins remaining soluble, left a deposit on the hide which could not be removed, and finally caused the finished leather to turn red on exposure to the air. The actual loss, including the original insolubles, was fully 25 per cent. of the quebracho extract used.

The analysis just given shows that quebracho extract contains one part of insoluble to every eight parts of soluble tannin. It was these insolubles which first attracted the tanner's attention. They not only represented a loss of more than 10 per cent. of extract but spoiled his leather. He did not know, and comparatively few tanners even now know, that in addition to the loss of the actually insoluble tannin there was a still greater loss of the really soluble tannins when mixed with the sour liquors of the tan-vat, but he knew enough to make him very chary of using quebracho extract, and in consequence, the manufacturers and handlers of quebracho at once set to work to get rid of the "insolubles." It would be tedious to enunciate all the different methods adopted for this purpose. I will mention only a few. The German tanner avoided the difficulty by not using extract at all. He went to the expense of bringing quebracho logs six thousand miles from Argentina, rasping them into "Loh Schnitt," and adding this "Loh Schnitt" directly to the cold tan-vat—by so doing he avoided the extraction of the "resinous and difficultly soluble" tannins, and was therefore not troubled by them. He threw them away. The extract maker did the same thing by leaching at a low temperature. He also tried "settling out" the thin liquor before concentration and throwing away the "insolubles" as mud. He tried precipitation with alum, precipitation with albumen, and precipitation with lead acetate; in every case the precipitate was thrown away as a useless nuisance. Extracts made by these processes were sold as "decolorised" or "clarified." They were more costly and but little better than the ordinary extract, because their soluble tannins were still precipitated by the sour liquors of the tan-vat. Practically they were but little used. The only recognition of the value of the "difficultly soluble tannins," and the only attempt to save them by solution, was that which was originally made, we believe, by some Italians, who dissolved the insoluble quebracho in an alkali, preferably borax. This method seemed so rational that we, ourselves, actually paid a royalty on several hundred barrels of extract so treated, and at least one American tanner used the process for several years in his tannery. But the high cost of borax, the necessity for after treatment with sulphuric acid, and the very justifiable prejudice of the tanning world against alkaline liquors finally gave the "coup de grace" to an impractical process. Such an important problem, however, was bound to find a solution. The honour is due to Italy. Two Italian chemists, Lepetit and Tagliani, after long experimenting, discovered that the sulphurous salts of the alkali metals, such as sodium sulphite, bisulphite, or hydrosulphite, would so perfectly dissolve the "reds" of quebracho extract as to keep them soluble, not only in cold water, but in the acid liquor of the tan-vat. They found also that these salts so acted on the soluble tannins of quebracho extract as to prevent their precipitation in sour liquors; in short, they found that by treating quebracho extract with sodium bisulphite or other sulphites under suitable conditions, all loss of soluble tannin was prevented and all the insoluble or "difficultly soluble tannins" were made available by solution.

The application of this discovery to quebracho extract eliminated all of its objectionable properties, made its use possible under all tanning conditions and in combination with the sour liquors of all other tanning extracts, thereby adding fully 25 per cent. to its value by saving and utilising the tannins which had previously been precipitated and thrown away. In fact, it is not going too far to characterise this discovery as one of the most important ever made affecting the leather industry.

The effect of the treatment with sulphites is shown by the two following analyses:—According to J. Gordon Parker, an ordinary solid quebracho extract has the following constituents:—Water, 21.10 per cent.; soluble tannins, 61.60 per cent.; insolubles, 10.00 per cent.; non-tannins, 7.30 per cent. According to the same

authority, the solid argam extract, which has been treated by the sulphite process of Lepetit, shows the following results:—Water, 21.50 per cent.; soluble tannins, 65.70 per cent.; insolubles, 0.00 per cent.; non-tannins, 12.80 per cent. It appears, therefore, that the sulphite treatment has increased the amount of soluble tannin from 61.50 per cent. to 65.70 per cent., and that of the non-tannins from 7.30 per cent. to 12.80 per cent., while the insolubles have totally disappeared, the moisture remaining the same in both cases. It is true also that 100 lb. of ordinary extract yield 110 lb. of treated extract, and that the treated extract is unaffected by the sour liquors of the tan-vat, but this, of course, is not shown by the ordinary analysis.

Their success with quebracho led the inventors, Lepetit and Tagliani, to try the same treatment on other tanning extracts. To their surprise, they found exactly opposite results. They found that the sulphite treatment has no good effect on chestnut extract and mimosa bark extract, their tannins remaining practically unaltered. It actually decomposed and partially precipitated the extracts of oak bark, sumac, valonea, myrobalans, and pine bark. After most thorough experimenting they found quebracho extract to be the only one employed in tanning that is practically benefited by treatment with the salts of sulphurous acid, and hence they confined their claims in U.S. Patent No. 799,246 specifically to the treatment of quebracho extract.

Years ago Foley took out a patent for preserving hemlock extract by treatment with bisulphites, so that fermentation would not take place during transportation. He succeeded too well, for he also prevented fermentation in the tan-vat, and thereby rendered the hemlock extract absolutely useless. His process was never practically applied on that account, and so far as my information goes, there is not now a sulphited hemlock extract on the market and never has been.

Lepetit and Tagliani patented their discovery in Germany and other European countries in 1896. The United States Patent was not issued until 1905, but in the meantime they arranged with H. Renner & Co. to use their process in Germany, with the right to sell the product in the United States. On Dec. 4th, 1900, Renner & Co. sent us the first sample of liquid quebracho extract, treated by Lepetit's process in a slightly modified form. It seemed to be what we had been looking for, and we at once ordered 10 tons for practical trial, which were invoiced April 27th, 1901. With the exception of a few casks shipped by Messrs. Lepetit, Dolfuss, and Gansser, of Milan, on March 11th, 1897, for the Durio Experiments in Newark, N.J., I believe this to have been the first "sulphited" quebracho extract imported or used in the United States. The trials were successful, and we continued importing the liquid extract in increasing quantities, in spite of the high specific duty of $\frac{1}{2}$ c. per lb.

In January, 1902, we received from Renner & Co. the first sample of "Krone" or sulphited quebracho extract in solid form, and at once ordered 30 tons, which were shipped on Feb. 24th, and was the first solid sulphited extract used in the United States. The quality proved so acceptable that on April 22nd, 1902, we contracted with Renner for 400 tons of the same extract, and we continued buying in steadily increasing quantities until Sept., 1903. Meanwhile we had contracted in October, 1902, for 7,800 tons of the same extract, to be made in South America. We received the first shipment on this contract on Aug. 31st, 1903, and commenced selling the Krone or sulphited quality of "argam" extract. We are selling the same extract to-day.

In 1901, before Lepetit's discovery came into practical use, the entire consumption of quebracho extract in the United States did not exceed 5000 tons of solid quality. In 1907, six years later, it was over 50,000 tons, chiefly sulphited. In 1909, it will probably be nearly 70,000 tons. How the production of extract in the wilderness of Argentina kept pace with the consumption brought about by the sulphite process has been almost marvellous. About twenty-five years ago, two young tanners, Carlos and Albert Hartenack, came to Argentina and becoming interested in quebracho, began exporting the wood to Havre, and in the course of time made long and arduous

explorations of the Argentine wilderness known as the "Chaco." Eventually they made extensive purchases of the best quebracho producing lands in Argentina. In conjunction with Renner in Hamburg they erected an extract plant with the best and most modern equipment at Calchaquí, in the heart of the quebracho forests of Santa Fé, with a capacity of 10,000 tons solid extract yearly. They commenced shipping ordinary extract in April, 1900, and continued to do so during the years 1901 and 1902 to the extent of about 5000 tons yearly. In 1904 the Messrs. Harteneck took into association with them the Brothers Portalis, of Buenos Aires, large owners of quebracho lands, and formed the "Compania Forestal del Chaco," to operate the Calchaquí works and build a new plant with a capacity of 20,000 tons yearly, some 300 miles north of Calchaquí, and still further in the heart of the Chaco wilderness. Not only an extract plant, but a town, and 50 miles of railroad, had to be built also. In May, 1905, this new Villa Gullermina began shipping extract to the United States, whose requirements meantime had increased to 18,000 tons yearly. In 1906 a third plant was erected in Gallareta, with a yearly capacity of 7000 tons, while the United States consumption went up to 30,000 tons of Argentine extract, in addition to the liquid extract made by the two American factories. Since then the Forestal Company has been merged into the "Forestal Land, Timber, and Railways Co., Ltd.," with a capital of nearly two million pounds sterling. The 7000 ton works at Puguahó have been purchased by this Company, and the capacity of Calchaquí increased to 14,000 tons. At present the Forestal Land, Timber, and Railways Co. operates four plants, with a capacity of 50,000 tons of extract yearly.

To supply these plants with wood and market their products requires 100 miles of railway, a fleet of boats on the Parana River, 1500 men in the factories, and 5000 men in the forests, working with 12,000 oxen and 1000 waggons.

I have gone into these details because in the last five years eight other extract plants have been erected in Argentina and Paraguay for the manufacture of unsulphited or "ordinary" extract only. Although they have a capacity of 40,000 tons yearly, they have probably never turned out more than 25,000 tons in one year, and even this quantity they have been unable to market at a profit. In consequence of the panic of 1897, the duty paid price of their extract in this market declined from 4 c. to 3 c. per lb., and even at this price the bulk of what was sold was afterwards sulphited either by dealers or the consumers themselves. Meantime the price of treated extract has scarcely varied, and is to-day at the maximum figure ever reached. No better proof of the value of the chemical treatment of quebracho extract by the sulphite process could possibly be furnished than this commercial fact.

DISCUSSION.

Mr. YOCUM said that the author had not described any method of treating quebracho extracts to make them soluble. Failures had attended the use of these extracts that were not soluble, and, latterly, success had attended the use of those that were soluble. It took years to find out that they were made soluble by treatment with sulphites.

The great difficulty with tanning chemists was that their measure of tanning values was empirical. They considered everything that was absorbed by hide, under the conditions of the test, was tannin. But other materials were absorbed which did not precipitate gelatin, such as glucose, and these did not tan leather. The ultimate determination of the value of a tanning extract must rest with the tanner himself through experiment, and while analyses might indicate the percentage of material present which would combine with the hide, the tanner himself must determine how much of this he could utilise under the methods he pursued.

Prof. ROGERS said that about a year ago, he had occasion to examine a substance called "T. Glutriu," a refuse of the sulphite process. This contained 25 per cent.

of tannic acid. It would tan leather, but the leather afterwards was like blotting paper. Had the author had occasion to use this product, and with what results?

REINFORCED CONCRETE INDUSTRIAL BUILDINGS.

BY J. P. H. PERRY.

The purpose of this paper is not to go into the history of concrete nor into the theory of the calculation and design of reinforced concrete, but rather to take up, one by one, the questions which owners of manufacturing plants raise in regard to this material.

Perhaps the most common point which is raised in connection with the construction of reinforced concrete buildings is the possibility of attaching shafting and piping in their proper place economically; and, also, in regard to making changes in the lay-out of these most necessary parts of the average plant. The illustration shows different methods of hanging shafting and machinery in reinforced concrete buildings. It is apparent from a study of the various schemes included in this figure, that piping or transmission lines can be provided for in concrete structures quite simply. A valuable comment on this topic is the fact that many industrial executives have not hesitated to duplicate reinforced concrete factories in the same material. Five large mill and manufacturing concerns have awarded six and more contracts for reinforced concrete buildings in the past four years. This would indicate positively that they had experienced no serious difficulties with shafting or piping. In fact, reinforced concrete construction tends to maintain shafting in position better than most other types of buildings. One large manufacturer of paper goods in New York has stated that his reinforced concrete factory saves him annually about \$5000.00 in repairs to his machinery and shafting, due almost wholly to the fact that the shafting or the machines once set in position on concrete beams or floors remain immovable, which, of course, results in less wear on bearings and moving parts. Shafting may be shifted easily in concrete buildings if proper provision has been made in the design of this structure. The cast iron spool sockets or the pipe holes through the top of the beam or the anchor plates may be placed in the beams at intervals of say five feet at the time the concrete is poured, thus providing means of supporting the shafting wherever desired. If no supports have been placed in the ceilings at the time of construction, the rearrangement of piping or shafting is accomplished most conveniently by setting expansion bolts in the sides of the beams and using iron hangers as shown in the figure.

Not infrequently the reinforced concrete advocate is told by a prospective builder that concrete is too strong. If the owner wants to build additions or to make alterations in his plant, the cost of ripping out concrete walls is so much greater than with brick walls that he will not authorize the use of concrete construction. It is undoubtedly true that concrete walls are more difficult to remove than brick. In the ordinary building the basic idea is to put up a permanent structure. Where, however, there is a probability of having to remove partitions or walls, it is possible to erect a reinforced concrete structural frame consisting of columns and floors and fill in the walls with brick or terra cotta. There are a great many plants in this country where all the buildings are of brick or stone, occasionally of the same general architectural treatment. The owner does not wish, in erecting his new building, to put up a white concrete building, which would contrast sharply with the rest of his establishment. To meet this condition, concrete buildings are designed much the same as structural steel, a skeleton framework being run up, and light non-self-supporting curtain walls of material similar to the exterior of the surrounding buildings being built in afterwards, or if there is a prejudice against concrete appearing anywhere in the exterior of the building the wall columns can be veneered. For the more typical factory construction reinforced concrete is to be recommended for the floors, beams, girders, and columns, and either brick or terra cotta walls—non-self-supporting—put in temporarily, so that in event of

extensions they can be removed without effecting the structural part of the building. The cost of a concrete wall compared with a brick wall under such conditions is dependent upon the thickness of the wall. Generally, unless local building laws interfere, good practice dictates the use of an 8 in. concrete wall in place of a 12 in. brick wall. In this case the cost of the concrete wall is slightly less than the brick. Where, however, the concrete wall has to be the same thickness of the brick, the brick, on the present market conditions in America, is cheaper.

Sometimes the question is raised that there is liable to be considerable vibration in reinforced concrete buildings. On what basis this idea is founded it is difficult to understand, because there are practically no cases known to reinforced concrete engineers and constructors where the vibration set up in reinforced concrete buildings was serious, and certainly not as bad as it would have been in other types of buildings. Where a long series of heavy presses or similar machines are set in position on one floor, all working in the same direction, there is likely to be a sway of the whole building, but this is true of any type of structure. The majority of owners of concrete plants are well satisfied that they get less vibration with this kind of construction than with any other kind of building. This is due primarily to the homogeneous and rigid form of construction. A reinforced concrete building properly designed and erected is monolithic and solid to an extreme degree. Heavy machinery may be set in place on the upper floors of an eight or nine story building and operated at full speed without producing any effect in the lower stories. A particularly striking instance of this may be cited in a building in Brooklyn, where the general offices are on the eighth floor, and under one desk, about the middle of the building, on the ceiling below, is bolted a 40 h.p. electric motor. The superintendent of this factory states that he doubts if the man at the desk over the motor is aware that the machine is directly under him. Certainly, unless he has been told of its existence, he would have no cause for knowing that it is there. This question of vibration in concrete buildings is one of the main reasons which have led to its adoption for structural purposes in so many industrial plants in this country. The absence of vibration reduces the repairs on machinery and permits of their operation at higher speeds than the more conventional class of building.

Reinforced concrete floors are occasionally objected to, because of the imaginary difficulty of cutting through them in event of having to run pipes or belting or wiring in places not originally intended. A concrete floor is, of course, hard to cut through, but the task is not insurmountable, and when compared to cutting through terra-cotta or brick floor arches, it is less serious in its results. Owing to the reinforcement running through floor slabs, generally in both directions, it is possible to cut through a floor at any point, except directly over beams or girders, without endangering the strength of the floor. It is hard to imagine cutting a hole of any magnitude through a terra-cotta floor or a brick arch without making some provision to take care of any loads which might be applied near the hole. Reinforced concrete floors are generally, in conservative practice at least, designed as simple beams, where as actually there is continuous beam action and not infrequently plate action, so that stresses are taken care of by the transverse or longitudinal reinforcement, when cutting has to be resorted to, in a manner not originally depended upon in the calculations. The experience of several large reinforced concrete construction companies, extending over a period of seven or eight years, and covering probably from 1000 to 1500 buildings erected of this material, shows no especial complaint on the part of the owners or architects on this score.

It is not often that there is much question as to the load-carrying capacity of reinforced concrete floors, but in case there is doubt in the minds of some industrial men as to the strength of reinforced concrete construction, it may be proper to cite a few instances showing the great efficiency of this character of construction along this line. Reference was made in the previous paragraph to the basis of design of floors, taking account of only the most conser-

vative stresses. A factor of safety of four is used, based upon rather low ultimate strengths of the material, so that reinforced concrete as erected is a great deal stronger than the calculations would indicate. There is no better proof of this statement than that furnished by an embossing press weighing 16 tons, resting on a base 3 ft. wide by 6 ft. long, having an area of 18 sq. feet. The load produced by this press is, therefore, but slightly under 1 ton per sq. ft. This press is located about in the centre of a column bay on the seventh floor of the Robert Gair Company Building in Brooklyn, the floors of which building were designed for a live load of 250 lb. per sq. ft. There has been no provision made to distribute the excessive load of the embossing press, nor has any bracing been resorted to in the floor below. This floor consists of a 4 in. reinforced concrete slab spanning between 7 in. by 15½ in. reinforced concrete beams spaced about 5 ft. 6 in. on centres. This press has been in position now for something over 18 months without there having been any noticeable deflection and without cracks showing. Another case of extreme loading without injury to the reinforced concrete is to be found in the J. B. King & Co. plaster mills at New Brighton, Staten Island, where floors designed for 600 lb. live loads, carry from 1200 to 1500 lb. over large areas. There are many other structures that might be cited where the loads sustained by the concrete run three or four times in excess of the figures used in the design. There need be no hesitancy on the part of the prospective builder to adopt concrete where his requirements call for the very heaviest loading. Certain grain elevators in Buffalo have reinforced concrete floors designed for 5000 lb. per sq. ft., and hardware storage houses in the North-West carry loads of 2000 lb. per sq. ft. Such strength as this is, except in the rarest instances, more than sufficient for industrial buildings.

There is a general idea that concrete walls are damp. Very probably this is due to the experience of many house holders with poorly made concrete blocks. It does not apply to properly constructed reinforced concrete industrial buildings. The company with which the writer is connected, has constructed probably one hundred buildings of this material during the past seven years, and has had no complaints on the score of dampness penetrating through the walls. The normal thickness of walls of this material is from 8 in. to 12 in. When made of wet concrete, as is customary, they are homogeneous and very nearly impervious after having dried out. This drying out takes, depending upon the weather, from three to six months, and is generally accomplished by the time the building is ready for occupancy. As a comparison between brick and concrete for wall construction, it is interesting to note that in several instances where buildings have been erected with both concrete and brick walls, each 12 in. thick, neither walls being water-proofed, the brick walls have shown dampness after storms while the concrete walls have given no trouble whatsoever. Condensation is experienced with concrete, and for residential work would be a serious fault, but for the ordinary industrial building the trouble is not grave. In plants where dryness is essential—such, for instance, as piano factories, where the wood stock is exceptionally dry and must be kept so, the slightest dampness being fatal—concrete buildings have been found to give excellent service. There is less condensation on concrete walls 12 in. thick, owing to the extreme non-conductivity of the material, than there is on brick walls of similar or slightly greater thickness. In typical reinforced concrete industrial buildings condensation appears only on the under side of the roof. The walls, being about 12 in. thick, remain at a fairly uniform temperature on the inside, whereas the 3 in. or 4 in. roof slab changes with exterior weather conditions. Usually slight condensation under the roof is of no importance, but if it were, a hanging ceiling could be installed at low cost.

In certain industries wooden floors may be necessary. This condition does not interfere with the selection of reinforced concrete as the structural material for many new buildings. The bearing slab between the concrete beams and girders would be constructed as in the ordinary reinforced concrete building. Instead, however, of giving this bearing slab a granolithic finish, it would be left rough

and when hardened a cinder concrete fill would be laid on top and wooden sleepers imbedded therein. The maple flooring would then be put in position. The most common reason for specifying wooden floors is the possibility that the operatives will object to standing on a concrete surface. This dislike of concrete on the employee's part was always a matter of prejudice and now is very largely overcome. There are so many mills and factories having concrete floors whose managers experience no complaint on the part of their working force, that the majority of new buildings of this type do not have wooden floors.

With regard to this question of floors in concrete buildings, attention may be called to the sanitary conditions set up in reinforced concrete buildings. Where wet processes are used or where washing of floors is necessary, concrete surfaces are easily the best for the purpose. Wood when wet frequently tends to decay and offers a harbouring place for vermin. Concrete buildings are notable for the absolute elimination of this pest. Concerns whose products or whose raw materials are perishable have found a considerable annual saving due to the absence of mice, rats, and bugs in their concrete buildings.

Reinforced concrete construction has very generally become accepted as fireproof in a high degree. Little discussion of this feature is necessary. San Francisco and Baltimore tested the material and found it good. Smaller fires, such as those at Dayton and Bayonne, subjected concrete to even more severe conditions, and those under the eyes of keen observers. The result is best expressed by insurance rates. The most alive insurance companies, as represented by the Mutual concerns of New England, advocate reinforced concrete construction enthusiastically and state they will write lower rates on buildings of this type than on any others. For instance, on a large paper factory in Brooklyn, made of reinforced concrete, the rate on the building is 12.2 c. per \$100 of insurance, and on the contents, 29.6 c. Across the street, belonging to the same company, is a first class mill constructed building. Under the same conditions of occupancy, use, hazard, and protection the building rate is 21.4 c., and on the contents 65.6 c. is asked. The annual saving is apparent.

After a fire, speed of construction is the first consideration. Reinforced concrete under no other condition so well fills the requirements. Work can be undertaken as soon as the ruins of the old structure are cleared away, and while footings are being placed the detail plans can be worked up and the building carried up to completion at a speed equal to or faster than with any other type of fireproof construction. With structural steel the columns and other members have to be designed in detail, rolled, fabricated, and delivered to the job before work can be prosecuted at full speed. Small steel bars for reinforcing purposes are always to be found in stock and need no assembling before shipment. Cement likewise can be started jobwards on short notice. Lumber, sand, and stone are locally obtainable. The advantage thus secured at the start of the new building more than overcomes a subsequent higher rate of speed with steel construction. The comparison applies somewhat similarly to mill construction. The large size wooden members essential to this slow burning construction are getting more difficult to procure and take valuable time before delivery. That concrete can be erected rapidly may be news to some, but when such speed as the roof on the seven story and basement Mason Warehouse in 48 days after the completion of the excavation; and the roof on the Bush Factory No. 3—600 ft. by 75 ft.—six stories and basement—in 63 days; and the roof on the ten story and basement Rogers and Pyatt Factory—60 ft. by 70 ft.—in 47 days after the foundations were in place, are cited, the facts must be recognised.

To those who have studied concrete or who are familiar with its properties, any doubt as to its durability seems unwarranted. Scepticism is sometimes expressed, however, on this point, and, also, as to the reliability of the material. In answering the first of these questions reference is generally made to the use of concrete in Egypt, Crete, or in the Peninsula of Yucatan, but the writer prefers to cite structures which he personally has seen. At Amalfi, Italy, there is a small foot bridge which was built by

the Turks in about the fifth or sixth century. The concrete of which this little arch is built is in a good state of preservation to-day and speaks eloquently for the lasting qualities of this material. In Rome, the Pantheon Dome is unmistakably concrete, and constitutes the most striking object lesson in this subject that there is to be found. When consideration is given to the fact that the cement used in those days was a natural cement of irregular composition and uncertain quality, little fear need be maintained for the concrete structures of the present day, which are made of Portland cement with uniform composition and careful manufacture. Belief in the reliability of reinforced concrete construction has perhaps been shaken in the minds of some people by certain failures of buildings erected of this material in different parts of the United States. The number of failures, however, in proportion to the amount of successful concrete work, is very small, and when investigated, these failures have all been traceable to ignorance, inexperience, and faulty design, not to any inherent fault of the material or to the method of construction. When a steel building collapses or a great bridge fails, when brick walls crack or masonry structures fall, those structural methods or materials are not decried, nor are they assailed as being dangerous, experimental, and unworthy of use. Reinforced concrete is a new material, one which has great possibilities and therefore attracts many contractors and builders who lack proper experience in its use. Mistakes under such conditions are bound to occur, but where experienced, skilful companies are employed, ideal buildings are the result.

The final consideration in the selection of the type of the new building is the question of cost. Briefly, under present market conditions in this country, reinforced concrete industrial buildings will cost from 10 to 20 per cent. less than the same building erected in structural steel fireproofed, and will cost from 5 to 20 per cent. more than first class mill construction. These percentages are not theoretical; they are based upon facts. For example, a large warehouse in Brooklyn was begun in May, 1908. At that time new construction work was scarce, and all contractors, both in the concrete and steel lines, figured very closely in order to secure the job. The successful reinforced concrete figure on this particular building was \$30,000.00 lower than the best bid received on the same plans executed in fireproofed structural steel. A large factory in Philadelphia was designed in steel and estimates received on the original plans. The architects considered an alternative in reinforced concrete construction and saved the owner \$60,000.00. A large publishing house and loft building was recently completed in Springfield, Mass., of reinforced concrete throughout, thereby saving \$40,000.00 over the probable cost in steel. These three instances represent respectively savings of 12, 25, and 10 per cent. In competition with mill construction the percentage depends almost entirely upon the size of the building. For structures costing \$40,000.00 and less, and of a height of four stories or less, the brick and wood construction will run about 15 per cent. less than concrete. On larger size buildings, however, concrete gets closer to the cost of the mill construction. The designers of a very large hardware building in Minneapolis took estimates on both reinforced concrete and mill construction. They were surprised to find that the concrete figures were slightly under those of the mill construction. A similar case occurred in Toledo, Ohio. Both of these propositions, however, exceeded \$250,000.00 in value.

In considering the costs of different types of construction the initial cost should not be the only criterion. There are certain fixed charges which enter into the relative values of buildings. These may be briefly summarised as follows:—Insurance, maintenance, depreciation, amount of light available, freedom from vibration, elimination of vermin, and the assurance that a fire cannot destroy the building. It is difficult to put an exact monetary value on these different items. Each plant manager would have his own views on the subject and local conditions would alter materially any assumptions. If, however, due consideration be given to the saving which can be obtained on each of these items by the use of a reinforced concrete building, it will generally be found that even though

the concrete structure cost complete 10 per cent. more than if mill construction had been used, there will be a saving annually of from $1\frac{1}{2}$ to 2 per cent.

In deciding to adopt reinforced concrete construction the owner will not be making an experiment. Reinforced concrete is an established material of recognised merit. Its development has been rapid, but, like that of another great modern art, viz., the electrical industry, it has been from the laboratory and scientist to the practical man, and not haphazard practice first and investigation afterwards. When the great Quebec bridge collapsed a short

time ago the engineering profession awoke to the fact that it knew little or nothing about steel columns from actual experiments and tests. Reinforced concrete has received rigid examination, and this careful study led Professor Burr, Consulting Engineer on the Panama Canal, to state publicly in writing that more was known about reinforced concrete as structural material than was known about steel. The number of monumental concrete structures which are going up all over America to-day preclude any experiment on the part of a man selecting reinforced concrete for his new building.

PATENT SPECIFICATIONS may be obtained by post by remitting as follows:—

English.—8d. each, to the Comptroller of the Patent Office, C. N. Dalton, Esq., Southampton Buildings, Chancery Lane, London, W.C.
United States.—1s. each, to the Secretary of the Society.

French.—1 fr. 25 c. each, to Belin et Cie., 56, Rue des Francs Bourgeois, Paris (3e.).

German.—1 mark each (with full particulars) to Kaiserlich Patentamt, Berlin, Germany.

I.—PLANT, APPARATUS, AND MACHINERY.

Special drying plant wanted for India. From Director-General of Commercial Intelligence, 5, Clive Street, Calcutta, India, 1909. [T.R.]

In the rainy season certain industries in India suffer from the difficulty of drying their products or materials. At times the air is saturated or nearly so, so to get it to take up more moisture high temperatures must be used, which are not permissible in certain cases.

An example of this is furnished by the flour-milling industry in India. Before wheat in a dirty state can be milled, it must be not only screened and scrubbed but washed, and the process of subsequent drying is troublesome, costly, and at times injurious. The usual method is that the wet wheat, after passing through a centrifuge, is discharged into the head of a vertical shaft containing baffles, and as it descends it meets an ascending current of increasingly hot air from gills that are heated by steam. This method is successful except in the rains; but during the rains the wheat must be let go with an excessive percentage of moisture, seeing that an indefinite intensification of the heat results in destruction of the starch globules and consequent injury to the flour.

The tanning industry would also gain greatly by an appliance that would dry the air in the monsoon without reliance on condensation processes. In one large tannery in India no attempt to dry hides is made during two months of the year. In some parts of the country the most serious difficulty is that of retarding the drying of the hides during the hot weather. At other seasons drying is artificially and very slowly effected by the use of steam pipes. The hides are suspended over and about these pipes; but the saturation of the atmosphere is such that the drying process occupies a number of days. During that time the hides have to be frequently wiped to free them from the moulds that grow profusely under such conditions; but those moulds work considerable mischief, and although they be superficially removed they may leave their spores in the leather to germinate so soon as favourable conditions recur, as they frequently do in India.

In the manufacture of sugar, deterioration in colour results from the creation of invert sugar during drying. The drying of sugar after it leaves the centrifuge is commonly effected by means of a cylinder that is heated by steam and rotates upon an inclined axis. But when the air is virtually saturated a disproportionate expenditure of heat is necessary to impart to it any drying power. So also in the drying of copra and in the desiccation of plantains for meal and of various substances for the production of starch. Several of these substances are not only peculiarly liable to decomposition and discolouration through prolongation of the process of drying, but are also sensitive as regards excessive heat. In all these cases the drying is conducted or attempted by raising the temperature of a damp air to such a point that it may be enabled to assimilate more moisture. But in proportion as the humidity of the air increases, any increment in temperature becomes more injurious. It would therefore be preferable to desiccate the air and pass it over the goods to be dried.

The desiccation of air for use in blast furnaces is conducted by lowering the temperature of the air so as to precipitate a proportion of the moisture it contains, as follows:—Pure liquid ammonia is contained within the ammonia expansion pipes in the air cooler, and by the action of the compressor pump a reduction of pressure is main-

tained within them causing the ammonia to pass off in the form of gas, and in so doing it takes up heat from the air in the cooler in which the pipes are placed, so reducing the temperature to any desired extent. The gas containing the heat thus abstracted enters the pump, and is passed by it into the condenser tubes where, by the action of the condensing water passing over them, and the pressure of the gas within the same, maintained by the action of the pump, liquefaction takes place, at the same time giving up the heat it contained to the current of condensing water passing over the condenser. The liquefied gas returns to the ammonia expansion pipes by a small pipe, and is controlled by a regulator. The whole action is automatic and controlled by the speed at which the compressor pump is worked.

Now, air so desiccated, if to be used for drying goods, would be raised to the highest non-injurious temperature in order that it might carry off a large quantity of moisture. This process is open to several objections. In the first place moisture is eliminated from the air merely by the elimination of the faculty of retaining the moisture, and therefore by the sacrifice of the power of acquiring moisture or performing any function of drying. In other words the latent heat is lost at each operation and has to be replaced at the cost of fuel. This defect is inherent in the process, but in India other difficulties peculiar to the climate are encountered. Not only do the high temperature and humidity encountered in India complicate the primal operation of desiccation, but they enormously increase the difficulty of subsequently liquefying the ammonia or other similar substance used. In the presence of approximate saturation of the air, the temperature of water in the open approximates to that of the atmosphere; and, since the high humidity also prevents any material reduction of the temperature of that water by evaporation while passing over the condenser tubes, it is a matter of difficulty to restore the ammonia to a liquid state.

The solution of the difficulty might be found in the employment of high temperatures to drive off the water of crystallisation from a substance that is not injured by heat, the air being thereafter dried by contact with that substance in its anhydrous condition, and then employed to desiccate at low temperatures such commodities as would not themselves stand heat. Such a substance must be highly hygroscopic and yet yield its water of crystallisation fairly easily. These properties are possessed by copper sulphate and by calcium chloride. The former develops at high temperatures a tendency to decompose and form basic sulphates, while it would be necessary to apply it as a "filling" of a porous vehicle such as coke. But such a vehicle could scarcely carry copper sulphate of more than 25 per cent. of its weight, or 20 per cent. of the whole, and great loss of power would be incurred by the repeated heating and cooling of a mass of which 80 per cent. was inert. On the other hand calcium chloride would be apt to deliquesce and disintegrate alternately during a process such as is suggested; but this might offer a positive convenience inasmuch as the substance in a liquid state would fall to the base of a suitable apparatus and might be drawn off for heat evaporation independently of any inert matter.

These facts and considerations are recorded in the hope that an engineering firm interested in the question may be induced to investigate it practically. As affording some indication of the extent to which a field already exists in India for an appliance such as is here outlined, it may be added that there are 30 flour mills, 15 sugar

factories, and 5 tanneries, in which the respective industries are conducted on a considerable scale. There are also other processes, such as wool-washing and the scrubbing of seed lse, to which an apparatus of the kind in question might be applied with advantage.

PATENTS.

Solution and precipitation processes; Apparatus for use in —. W. Hommel and The Metals Extraction Corporation, Ltd., London. Eng. Pat. 27,917, Dec. 6, 1907.

THE solids are introduced into the rotatable drum, A, through the manhole, C, and liquids through the pipe, D. Spiral channels, K, formed of angle-irons are arranged as indicated within both the cylindrical and conical portions of the drum to assist in the mixing. When sufficiently mixed, the materials are discharged through the valved opening, G, H. In some cases it is preferred to introduce the liquid through a perforated pipe which penetrates into the drum after passing through a stuffing-box. The perforated pipe is provided with a brush rotated with the drum to keep the perforations clear.

—W. H. C.

Kilns; Gas fired —. E. Schmatolla, Berlin. Eng. Pat. 5187, March 7, 1908.

THE heating chambers are arranged in a double row with a double gas flue constructed below the ground in the passage between the ovens. The flues are supplied with gas from a producer at each end and the ends of the flues can be opened to facilitate cleaning. The transverse branch pipes by which the gas is conducted into the heating chambers are not directly connected to the gas flues, but the connection is made by movable boxes and the flues are shut off by movable slabs which can be arranged from without. The flues which conduct the waste gases to the stack are similarly arranged.—W. H. C.

Retort and shaker and cooler; Combined —. J. S. Guibbini, Benicia, Cal. U.S. Pat. 915,428, March 16, 1909.

A RECEPTACLE is mounted on a shaker frame within a horizontal retort, provided with heating and cooling pipes, and supported on guides and springs. The movement of the shaker is effected by a reciprocating rod which passes through a stuffing-box in one end of the retort and which is operated by gear from without.—W. H. C.

Furnace. U. Wedge, Ardmore, Pa. U.S. Pat. 916,234, March 23, 1909.

THE claim is for a rotary furnace having several superposed stationary hearths and a central hollow rotating shaft. Each hearth is provided with one or more hollow stirrer arms, through which a current of air flows from the central shaft and from which the air passes to independent outlets.—W. H. C.

Evaporator. T. Suzuki, Sunamura, Japan. U.S. Pat. 916,054, March 23, 1909.

THE liquid to be evaporated is allowed to flow over the outer surface of a vertical corrugated cylinder and is received in a shallow pan placed below. The heating is

effected by the products of combustion from a furnace which pass upwards into the interior of the cylinder, over a centrally disposed, vertical baffle-plate and return downwards to the inlet of the next evaporator.—W. H. C.

Rectifier for distilling apparatus. E. Bonnel. Fr. Pat. 395,040, July 24, 1909.

THE apparatus consists of a system of hexagonal tubes immersed in the vessel, A, which is filled with water or other suitable liquid. The spaces between the walls of adjacent tubes are less than 0.5 mm. The vapours from the still, C, pass upwards between the tubes and are cooled by the water or other liquid which circulates in A, and in the tubes. The vapours of higher boiling point are condensed and flow back to the still and these of lower boiling point pass through B, to the condenser. The object of the invention is to obtain a large cooling surface without unduly increasing the size of the rectifier.

II.—FUEL, GAS, AND LIGHT.

- Pitch in coal-briquettes; Colorimetric determination of —.* K. Leo. Chem.-Zeit., 1909, 33, 359—360.

THE method described is applicable only if samples of the pitch and coal used in making the briquettes are available. It consists in treating 1 gm. of the finely-powdered and dried sample of the briquettes with 200 c.c. of boiling benzene in a flask attached to a reflux condenser, cooling the solution so obtained, rapidly filtering a portion through two filter-papers, and comparing the colour of 20 c.c. of the filtrate with that of a solution produced in a similar manner by the extraction of a mixture of 0.95 gm. of the dried coal with 0.05 gm. of the pitch. As a check on the results, which are accurate to 0.05 per cent., a second standard solution may be prepared from a 7 per cent. pitch-coal mixture.—A. G. L.

- The incandescence gas mantle industry.* Times, Eng. Suppl., April 14, 1909. [T.R.]

THE manufacture of incandescence mantles in Germany reached its highest point in 1906-7, and has recently declined, owing to the fact that England, France, the United States, and other countries have established factories. The industry, however, is still to a great extent in German hands, and the majority of the more important factories are established near Berlin. Competition between German manufacturers has lowered the prices of mantles until it now seems impossible to supply a really good article at a lower price; but the difference between a first-class mantle and one of an inferior quality is very marked. At present the maker who uses only the best material and most skilled labour, in order to supply a good article, suffers, because the public does not appreciate this difference in quality. The annual production of mantles for the whole world is distributed as follows, the figures referring to millions of mantles:—Germany, 100; America, 55; Great Britain (including Colonies), 35; France, 15; Austria, 3; Italy, 2; Belgium, 2; Russia, 1.

- Oxidation of hydrogen and carbon monoxide.* Orlow. See VII.

PATENTS.

- Bituminous binders and compositions; Producing —.* W. S. Wilkinson, Wytheville, Va. U.S. Pat. 915,260, March 16, 1909.

THE pitch or other binding agent is very finely ground and mixed with water or some other liquid in which it is not soluble. The resulting mixture is then incorporated with the coal so as to distribute the pitch thoroughly over the particles of coal, and the mass is dried, heated, and briquetted.—W. H. C.

- Coke-oven.* W. B. Smith, sen., Pittsburg, Pa. U.S. Pat. 915,630, March 16, 1909.

THE oven is built upon a framework of girders which supports it at some distance above the floor level. The bottom of the oven is detachable and is normally held in position by an elevator which is locked when the bottom is in contact with the oven. The oven is charged through an opening in the top and when the charge is coked, the elevator is lowered with the oven bottom on which the coke rests. When level with the floor the elevator tilts the bottom of the oven and the latter moves sideways on rails, carrying the coke with it clear of the oven structure. The coke is then removed and the oven bottom

is hauled back into position beneath the oven, raised into contact by the elevator and the latter locked, leaving the oven ready for the next charge.—W. H. C.

- Electric conductors suitable as filaments for lamps; Manufacture of refractory —.* W. D. Coolidge, Schenectady, U.S.A. Eng. Pat. 17,620, Aug. 21, 1908. Under Int. Conv., Aug. 24, 1907.

IN the manufacture of metallic filaments, the process of heating the filaments by the passage of a current in order to shrink and sinter them has hitherto required the separate treatment of each filament. The invention consists in connecting a number of filaments in parallel and treating them simultaneously with the current. The filaments are first partially shrunk by baking them so that the conductivity will not alter greatly during the treatment with the current; in cases where it is not desirable to bake the filaments to this extent, automatic regulating means are provided for maintaining the proper current through the individual filaments. In carrying out the process the partially shrunk filaments are mounted between spring clips supported on two conducting rails in a cylindrical treating vessel, the rails forming the leads to the filaments; an adjustable resistance is provided in the circuit. When regulating means are necessary for the individual filaments, one of the supporting rails is non-conducting, and each filament is connected in series with two or more iron wire resistances, having a positive temperature coefficient, such as are used in Nernst lamps. During the treatment of the filaments, as the conductivity of a filament increases, the resistance of the iron wire in series with it also increases and prevents the passage of an excessive current.—A. T. L.

- Incandescent body for electric glow lamps.* W. V. Bolton, Charlottenburg, Assignor to Siemens und Halske A.-G., Berlin. U.S. Pat. 915,657, March 16, 1909.

SEE Fr. Pat. 321,412 of 1902; this J., 1903, 206.—T. F. B.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, PETROLEUM, AND MINERAL WAXES.

- Wood; Destructive distillation of — with superheated steam.* G. Büttner and H. Wislicenus. J. prakt. Chem., 1909, 79, 177—234.

THE authors studied the destructive distillation of wood (red and white beech) and cellulose (filter-paper) with superheated steam, and also the distillation of cellulose with direct heating. In distilling with superheated steam, the material (wood, cellulose) was placed in one-half of a wrought iron tube, the other half of which served as steam superheater; the iron tube was heated in an electric furnace or in a gas furnace. In each test the yields of acetic acid, methyl alcohol, reducing substances (as acetaldehyde), ketones (as acetone), charcoal, tar, and gas were determined. The acetic acid was determined by acidifying with sulphuric acid, distilling with steam, and titrating the distillate with N/10 sodium hydroxide, using phenolphthalein as indicator; the methyl alcohol by Stritar and Zeidler's method (this J., 1904, 841); the reducing substances by heating with ammoniacal silver solution and ascertaining the amount of silver reduced; and the ketones by a modification of Denigès' method (this J., 1899, 179), hydrogen peroxide being added to the liquid before precipitation. It was found that cellulose when distilled under ordinary conditions or with superheated steam yields no methyl alcohol, but up to 2.5—2.8 per cent. of acetic acid. In the distillation of wood, acetic acid is formed from both the cellulose and the lignin, but methyl alcohol only from the latter. By using a sufficiently high temperature, cellulose can be completely decomposed by means of superheated steam leaving a residue of ash. The yield of reducing substances is about twice as high with superheated steam as with direct heating. In the distillation of wood with superheated steam, it is not advantageous to work at too high a temperature, so that the steam acts

exclusively chemically, as under such conditions, the yield of gas is increased at the expense of the charcoal and the liquid distillation products. It is preferable to use the steam rather as a medium which ensures the uniform distribution of the heat throughout the wood, thus avoiding local overheating. It is then possible to obtain excellent charcoal and a higher yield of acetic acid (about 10 per cent. on the dry wood) but less methyl alcohol than with direct heating. By heating rapidly to the distillation temperature, it is possible materially to shorten the time of distillation, but the yield of charcoal is diminished; the yields of reducing substances, tar, and gas increase, and that of acetic acid remains practically unaffected. It is possible to avoid excessive dilution of the distillation products by heating the wood gently before introducing the steam, and by collecting the products in

fractions; the fraction distilling between 240° and 300° C. contains nearly the whole of the valuable products. Destructive distillation of the wood begins at 240° C. The reaction is exothermic, but all danger of explosion can be avoided by blowing steam through so as to displace the air just before the temperature of decomposition (240° C.) is reached. By treating the distillate with oxidising agents such as hydrogen peroxide, the reducing substances are oxidised, and the yield of acetic acid increased. By using air as oxidising agent, however, either during or after distillation, the yield of acetic acid is diminished. Attempts to use heating with superheated steam on the large scale gave unsatisfactory results, but in view of the excellent results obtained on the small scale, the authors consider further work in this direction worthy of attention.—A. S.

Table showing the results of an examination, by the usual process of fractional distillation, of samples of seven different brands of petrol.

Naphthalene; New method of preparing β -halogen derivatives of —. G. Darzens and E. Berger. *Compt. rend.*, 1909, 148, 787—788.

SODIUM (1 atomic proportion) is pulverised by agitation with dry, boiling toluene, β -naphthol (1 mol. proportion), dissolved in dry toluene, then being added. Evolution of hydrogen proceeds smoothly, the mixture being finally heated on the water-bath until all the sodium has dissolved. Slightly more than the theoretical quantity of phosphorus trichloride or tribromide, diluted with toluene, is then added little by little; heat is evolved during this operation. The mixture is heated on the water-bath for an hour, then taken up with water and steam-distilled. β -Chloro- or β -bromonaphthalene is thus obtained in a state of fairly high purity. The yields are: β -chloronaphthalene, 55; β -bromonaphthalene, 38 per cent. With phosphorus pentachloride and pentabromide, the yields are only 3 and 21 per cent. respectively; with phosphorus oxychloride, no β -chloronaphthalene is formed, and with the oxybromide, the yield of β -bromonaphthalene is only 0.6 per cent. An attempt to prepare chloro-benzene and the chlorotoluenes by this method was unsuccessful.—L. E.

International Petroleum Testing Commission. Oil, Paint, and Drug Rep., April 5, 1909. [T.R.]

THIS International Petroleum Testing Commission will hold a meeting in connection with the International Congress of Applied Chemistry in London, beginning May 24, and meeting at intervals during the course of this Congress up to June 5. At this meeting the first work will be to make certain members responsible for the comparison of various methods of testing viscosity, determination of sulphur in oils, determination of flash-points, fire tests, determination of paraffin wax and asphaltum, etc., so that there will be as little as possible of duplication in work. Each oil-producing country is entitled to two representatives on the Commission, although a country has only one vote in the final decisions.

Petrols; Composition of commercial —. B. Blount. *Inst. Automobile Engineers*, March 10, 1909, 1—6.

SAMPLES of seven well-known brands of petrol were bought at different places in London in the ordinary way in sealed cans. The samples were submitted to the usual examination, the results obtained being given in the annexed table. The calorific value was determined in a bomb calorimeter, Berthelot's method for volatile liquids being used. This consists in placing the petrol in a relatively deep platinum cup, which is entirely enclosed in a "sack" of celluloid. Without this device it is impossible to ensure complete combustion of the petrol, although the explosion is very violent. It appears from the table that the calorific value for a given weight of fuel is nearly the same in all cases. Consequently, as petrol is sold by volume, there is an appreciable advantage in using the heavier grades, which have a higher calorific value per unit volume, provided that they can be burnt as efficiently. The percentage of sulphur is insignificant in all cases. As regards the figures given on fractionation, three of the brands examined, "Pratt," "Shell," and "Carburine," sufficiently resemble each other to make it possible to draft a specification for petrol of this grade which shall include all three brands. The other brands differ too widely to permit of useful grouping, but even the heaviest, "Anglo 760," with a sp. gr. of 0.735—0.740, has only a small proportion of distillate above 133°C. The lightest brand is "Carless Standard," with 98 per cent. distilling below 120°C. It is probably similar to the petrol of earlier days. (See Table, page 418.)

Trinidad asphaltum; Proximate composition and physical structure of —. C. Richardson. *Proc. Amer. Soc. for Testing Materials*, 1908, 6, 509—518.

TRINIDAD asphaltum, composed of bitumen in intimate admixture with clayey matter and a thermal water, is extremely uniform in its proximate composition. The usual method of analysis consists in drying at 100°C. for the determination of the water, treating with cold carbon bisulphide for the extraction of the bitumen, and

igniting the residue for the estimation of the mineral matter. The total so obtained, whether on the crude or the refined asphaltum, leaves about 7 per cent. unaccounted for and this deficiency, hitherto assumed to be "organic matter not bitumen," has been found to consist of the volatile constituents (combined water, alkalis, etc.) of the mineral matter, with a small percentage of bitumen retained by the absorptive or adsorptive power of the solvent-treated residue and expelled during ignition. The addition of tricalcium phosphate before ignition prevented loss of inorganic salts and resulted in an increase of 2 per cent. in the amount of mineral matter found, while the quantities of combined water and absorbed bitumen held by the solvent-treated residue corresponded respectively to 4.2 and 0.3 per cent., thus accounting for practically the whole of the deficiency observed in the results of the ordinary routine analysis. The strongly absorptive action of clays, etc., upon bitumen in carbon bisulphide solutions was found to be selective also: the higher hydrocarbons of the bitumen are absorbed in preference to the lower, the process being similar to that which takes place when crude petroleum is passed through clay for refining purposes.

As regards the physical structure of Trinidad asphaltum, the observations made and experiments described show that the water is held by the clayey matter, the definite ratio of water and clay being due to the capacity of the mineral matter for water; and that the deposit has been formed by the bitumen coming into contact with the original clay-mud of the Trinidad Lake. The definite ratio of mud and bitumen is accounted for by assuming that the mud has a definite capacity for taking up and holding bitumen.—W. E. F. P.

Hatchettin from Bonarka near Cracow. J. Morozewicz. *Anz. Akad. Wiss. Krakau*, 1908, 1067—1072. *Chem. Zentr.*, 1909, 1, 1113.

A VERY pure deposit of hatchettin has been discovered in a cretaceous marl at Bonarka, near Cracow. The mineral which consists of a solid paraffin of the composition, $C_{33}H_{78}$ (octatriacontane), occurs in small clusters of flaky structure and of a pearl-white colour with a tinge of yellow. It melts at 79.4° and solidifies at 78.9°C.; sp. gr., 0.961; hardness, 1.—A. S.

PATENTS.

Condensation products of wood-tar with formaldehyde; Process for the manufacture of —. W. P. Thompson, Bradford. [From K. A. Lingner]. *Eng. Pat.* 25,318, Nov. 24, 1908.

By the condensation of wood-tar with formaldehyde in presence of acid condensing agents, an almost odourless product is obtained, which does not colour the skin, is neither irritant nor poisonous, and possesses in increased measure the characteristic curative properties of wood-tar. According to the present patent, this condensation product is prepared in presence of an alkaline condensing agent. A mixture of 140 kilos. of wood-tar, 30 kilos. of soda lye of 40° B., and 80 kilos. of 40 per cent. formaldehyde is heated gently. When the reaction is complete, the viscous product is diluted with water and poured into a mixture of 500—600 kilos. of water and 18 litres of 25 per cent. sulphuric acid. The condensation product separates as light brown flakes, which are washed and dried.—A. S.

Tar oils; Process for purifying —. W. Feld. *Ger. Pat.* 208,190, May 15, 1907.

WHEN hydrogen sulphide and sulphur dioxide interact in presence of tar oils (see *Fr. Pat.* 387,438 of 1908; this *J.*, 1908, 810), the recovered sulphur is discoloured. This can be avoided if the tar oils are treated, either simultaneously or separately, with sulphur dioxide and hydrogen sulphide, and then distilled. The resulting oils smell of hydrogen sulphide; this is no disadvantage if they are to be used for the solution of sulphur, but if they are needed for other purposes, the odour can be removed by warming, or by passing air or sulphur dioxide through the oils, or by treating them with alkalis or alkaline-earths in presence of metallic salts, or with

metallic oxides or hydroxides. Instead of the treatment with sulphur dioxide and hydrogen sulphide, the oils may be treated before distillation with polysulphides or salts of thio-acids in presence of acidic compounds, such as mineral acids, carbon dioxide, phenols, etc.—T. F. B.

Bye-products from asphaltum and the like; Production of —. S. Everett, London. Eng. Pat. 27,335, Dec. 11, 1907.

THE claim is for the production of oils and other products from asphaltum by distilling the material placed in thin layers in long, wide and shallow retorts heated to a temperature of about 800° F. The heating is stopped when oil ceases to distil over and the residue is withdrawn.—W. H. C.

IV.—COLOURING MATTERS AND DYESTUFFS.

Indigo; A new isomeride of —. A. Wahl and P. Bayard. Compt. rend., 1909, 148, 716–719.

OXINDOL condenses with aromatic aldehydes yielding well crystallised, coloured compounds, for example, with piperonal a bright yellow compound, m. pt. 228°–229° C.,

of the constitution, $\text{NH} \begin{array}{c} \text{CH} \\ \diagup \quad \diagdown \\ \text{CO} \end{array} \text{C}_6\text{H}_4 \begin{array}{c} \text{O} \\ \diagup \quad \diagdown \\ \text{O} \end{array} \text{CH}_2$,

is formed. As this reaction seems to be general the authors suggest the name *iso-indogenide* for compounds

of the general formula, $\text{NH} \begin{array}{c} \text{C}_6\text{H}_4 \\ \diagup \quad \diagdown \\ \text{CO} \end{array} \text{C}_6\text{H}_4 \text{R}$. The

condensation of oxindol with isatin gives rise to a new isomeride of indigo and is carried out as follows: A solution of 1.35 grms. of oxindol and 1.5 grms. of isatin in 30 c.c. of acetic acid containing 0.5 c.c. of concentrated hydrochloric acid is heated on the water-bath. The solution turns brown and the dyestuff crystallises out. After 2 to 3 hours the reaction is finished and the dyestuff is washed with alcohol and ether and recrystallised from acetic acid, when it is obtained in brown red needles with a yellow reflex. This *iso-indogenide* of isatin, or 3:3-bisindolindigo, has the constitution,

it is insoluble in water, slightly soluble in the ordinary organic solvents in the cold but more readily when hot. From methyl alcohol it crystallises in flat garnet-red needles. Its solutions are brownish-orange with a red tint. It is insoluble in alkaline solutions of hyposulphite (hydrosulphite) but its acetic acid solution is decolourised by zinc powder. Similarly by condensing isatin chloride and oxindol by the process already published (this J., 1909, 238) Indirubin was prepared.—J. C. C.

Azo-dyestuffs derived from the aminosulphonamides; A series of —. G. T. Morgan and F. M. G. Micklethwait. J. Soc. Dyers and Col., 1909, 25, 107–111.
